Always try to transport a disturbed patient without restraints if possible. However, once the decision has been made to restrain a patient, you should carry it out quickly. Take proper standard precautions. If the patient is spitting, for example, place a surgical mask over their mouth and make sure you and your partner do the same.

Make sure you have adequate help to restrain a patient safely. *At least five trained, able-bodied people should be present to carry out the placement of restraints*, with each person being responsible for

one extremity. Before you begin, discuss the plan of action. As you prepare to restrain the patient, stay outside the patient’s range of motion.

When subduing a disturbed patient, use the minimum force necessary. Avoid acts of physical force that may cause injury to the patient. The level of force will vary depending on the following factors:

- The degree of force that is necessary to keep the patient from self-injuring or harming others.
- A patient’s sex, size, strength, and mental status.
- The type of abnormal behavior the patient is exhibiting. You should use only restraint devices that have been approved by the relevant authority in your area (sometimes the state health department). Soft, wide leather or cloth restraints are preferred over police-type handcuffs.

Acting at the same time, the law enforcement personnel should secure the patient’s extremities with approved equipment. Someone—preferably you or your partner—should continue to talk to the patient throughout the process. Remember to treat the patient with dignity and respect at all times. Also, monitor the patient for vomiting, airway obstruction, and cardiovascular stability: once restraints have been applied, the patient has a limited ability to protect the airway or otherwise compensate for physiologic changes. Drug or alcohol intoxication initially may cause violent behavior but then lead to physical problems such as vomiting or aspiration. Never place a patient facedown, because it is impossible to adequately monitor the patient and this positioning may inhibit the breathing of an impaired or exhausted patient. Be careful not to place restraints in such a way that the patient’s respirations are compromised. Reassess the patient’s airway and breathing continuously. You should make frequent checks of circulation on all restrained extremities, regardless of patient position (**FIGURE 24-3**). Document the reason for the restraint and the technique that was used.

Be especially careful if a combative patient suddenly becomes calm and cooperative. This is not the time to relax; rather, you should remain vigilant. The patient may suddenly become combative again and injure someone.

Safety

If you do not have five people to restrain a violent patient, you should call the dispatcher and request additional assistance.

FIGURE 24-3 Assess the airway and distal circulation frequently while the patient is restrained.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Keep in mind that you may use reasonable force to defend yourself against an attack by an emotionally disturbed patient. It is extremely helpful to have (and document) witnesses in attendance, even during transport, to protect against false accusations. AEMTs may be accused of sexual misconduct and other physical abuse in such circumstances.

Words of Wisdom

After restraining a patient, document the reason for doing so and the method you used. Check the pulse and motor and sensory function in all extremities, make any adjustments needed to ensure adequate function, and record your actions and findings in detail.

Posttraumatic Stress Disorder and Returning Combat Veterans

PTSD can occur after exposure to, or injury from, a traumatic event. Such events may include sexual or physical assault, child abuse, a serious accident, a natural disaster, war, loss of a loved one, or stressful life changes. People may have experienced fear of danger, helplessness, or a severe reaction during the event. The reaction could be to trauma that occurred long ago, or it may be the result of multiple traumatic events over time. It is not necessarily the result of one isolated or recent event.

It is estimated that 7% to 8% of the general population will experience signs of PTSD at some point in their lives.¹⁹ For health care workers returning

from a warfare environment, which could include disaster workers, threat of personal harm is considered a predictive factor in determining in whom PTSD will develop.

Military personnel who experienced combat have a high incidence of PTSD. PTSD occurred in 11% to 20% of veterans of the Iraq and Afghanistan wars, 12% of Gulf War veterans, and 30% of Vietnam veterans.²⁰ Reminders of their experiences in the military such as news coverage or gatherings of veterans can also be triggers.

Signs and Symptoms of PTSD

Symptoms of PTSD include feelings of helplessness, anxiety, anger, and fear. People with PTSD may avoid things that remind them of the trauma, including loud noises or smells, and sometimes they may avoid interactions with other people. This emotional and physical distancing from others can have a negative effect on the individual's quality of life. Memories of the trauma linger and continue to be disruptive. Symptoms of PTSD may be made worse in the context of other mental health challenges.

The sympathetic nervous system provides the fight-or-flight response to help protect us in a perceived dangerous situation. This mechanism is not intended to be activated for any longer than it takes to mitigate the threat. People with PTSD, however, suffer nervous system arousal that continues and is not easily suppressed. Heart rate increases to channel blood into the heart, lungs, and brain; pupils dilate; and systolic blood pressure is increased. Senses are sharpened and mental acuity is heightened. The patient may be hypervigilant or display an exaggerated startle response to perceived danger.

People with PTSD can relive the traumatic event through intrusive thoughts, nightmares, or even flashbacks. Flashbacks are uncontrollable events triggered by a sound, sight, or smell. The patient may experience the same visceral response as during the initial encounter with the stress. These episodes can last seconds or hours and can occur at any time, even years after the exposure. The person fears the inability to control a flashback and worries that it will present as irrational behavior. Recent traumatic events may also trigger old memories and create a reflex reaction of preparing for the worst. A person who has experienced flashbacks may become

preoccupied with the perception of danger. Hypervigilance and trouble sleeping are not unusual.

Dissociative PTSD occurs when the person attempts to find an escape from constant internal distress or a particularly disturbing event. The individual's altered consciousness allows them to continue functioning under negative conditions. Some people may undergo an out-of-body experience; others experience delusions. Other psychological conditions such as personality disorders and increased functional impairment can develop in those individuals with a dissociative subtype of PTSD.

Guilt, shame, paranoia, hostility, and depression are not uncommon in combat veterans. Alcohol and/or drug use often represents an attempt to suppress the sympathetic nervous system activity and slow down the body. This attempt at anesthesia can easily become addictive.

Suicide is sometimes sought to end the pain. Veterans are much more likely to harm themselves or try to harm themselves. According to the US Department of Veterans Affairs, more than 6,000 veterans take their lives each year.²¹ They also experience a host of physical conditions—some from injuries sustained in combat, and sometimes vague, unfocused pain not associated with any specific part of the body. This perception of physical pain may be a sign of their anguish. Combat veterans, in particular, may develop heart disease earlier than expected given their age, have a higher incidence of type 2 diabetes, and sustain a loss of brain gray matter. High cholesterol and hypertension are not uncommon and are often undiagnosed or misdiagnosed.

Another consideration for the combat veteran is the higher incidence of traumatic brain injury (TBI) sustained from trauma secondary to the explosion of an improvised explosive device (IED). In some cases, the TBI may go undiagnosed because its manifestations are similar to the symptoms of PTSD or because the patient downplays the symptoms. People with TBI can experience sensory dysfunction, confusion headaches, memory loss, and general disorientation. Memory loss can include retrograde and anterograde amnesia (affecting memories formed before and after the event, respectively).

When treating a combat veteran with PTSD, try to eliminate excess noise. Do not touch or do anything to the veteran without an explanation. Interestingly, diesel fumes can be a trigger for

Street Smarts

In a 2016 report published by the National Association of EMTs, *National Survey on EMS Mental Health Services*, most EMS providers surveyed felt affected personally by mental health issues. Take care of yourself, and watch those you work with for signs of depression and other mental illnesses. We need to take care of each other. Helpful resources on this subject include EMS Strong (www.emsstrong.org) and the Code Green Campaign (codegreencampaign.org).

combat veterans, so keep your diesel equipment far enough away that its odors are not noticeable by the patient.

Caring for the Combat Veteran

How do you recognize returning veterans? They often continue to adhere to their military identity by having short haircuts and wearing military clothing with combat patches, and many have military-themed tattoos. Their homes may have flags, memorials, commendations, and military photos. They may have a military appearance and use military vocabulary. They tend to show respect for authority but may be reluctant to talk to you about PTSD. They may not be aware that they have this condition, or do not want to be considered “mental.” They might have trouble asking for help. Questions such as “How do you want me to help you?” or “What do you need right now?” are good ways to open the conversation.

The returning combat veteran is a patient who will require a unique level of understanding, compassion, and specialized attention. These patients experience pain that is emotional as well as physical. You will need to take time to establish the history of this patient and listen to the patient's concerns. Approach this patient with sensitivity and respect. Be careful how you phrase your questions. “Were you in combat?” is an appropriate question, but in some cases, veterans may be in denial or do not believe they were in combat. A better question might be “Were you shot at or under fire?” If you served in combat, you can create trust by letting the patient know. Ask questions about the patient's service (eg, branch, rank). You may get enough information out of that conversation to eliminate probing with specific questions.

YOU are the Provider SUMMARY

1. Does this scene need to be treated differently than other scenes just because the patient has a mental illness?

This scene needs to be treated the same as any other call, with the exception of maintaining an increased situational awareness for the potential of violence. It is necessary to rule out the possibility of a medical cause being the reason for the patient's altered mental status.

2. Who has overall control of this scene, EMS or law enforcement?

This kind of situation requires coordinated management by all agencies involved. A mental illness call is not just a "law enforcement problem" or an "EMS problem," but rather a problem that takes a team approach to achieve the best outcome for all people involved.

3. This patient has a known history of mental illness. Does he need to be transported to the hospital?

This patient is having homicidal ideations and is a threat to others. He also has an extensive documented history of PTSD. This patient definitely needs to be evaluated in an emergency department.

4. Does this patient require an ambulance transport to the emergency department, or should law enforcement transport him?

Whether this patient requires transport via EMS or law enforcement depends on local protocols. Once all possible medical causes have been ruled out as the cause of his behavior, some agencies may defer transport to law enforcement. However, knowing who will transport patients such as this before the time comes is imperative to having a smoothly run scene.

5. What is the minimum number of providers who should be present when attempting to physically restrain a patient?

In an ideal environment, at least five providers should be present to physically restrain the patient: one provider to take each extremity, and a fifth provider to control the head. Using five providers will minimize the potential for any injuries, while still providing positive control over the patient.

6. In which position should this patient be restrained?

This patient should be restrained in the supine position. Under no circumstances should a patient be

transported restrained in the prone position because of the possibility of positional asphyxia.

7. Should a law enforcement officer accompany you in the back of the ambulance or should the officer follow behind the ambulance in the patrol car?

When a patient is restrained in handcuffs, it is necessary that the officer accompany EMS personnel in the back of the ambulance with the patient. This will allow for easy removal of the handcuffs should the patient's condition deteriorate. If the officer follows along behind the ambulance and there is an emergency that requires that the handcuffs be removed, an unacceptable delay in getting the officer into the back of the ambulance would result. Furthermore, placing the patient into handcuffs for his own protection is possible only if the officer effectively takes the patient into protective custody. The patient should therefore not be transported without being escorted by a law enforcement officer.

8. Is it possible that the patient may be suffering from a TBI?

Yes, it is possible the patient may be suffering from TBI. A consideration for the combat veteran is the higher incidence of TBI sustained from trauma secondary to the explosion of an IED. In some cases, the TBI may go undiagnosed because its manifestations are similar to the symptoms of PTSD or because the patient downplays the symptoms. People with TBI can experience sensory dysfunction, confusion, headaches, memory loss, and general disorientation. Memory loss can include retrograde and anterograde amnesia (affecting memories formed before and after the event, respectively).

9. If the patient is now cooperating, should you ask the officer to remove the patient's handcuffs?

Under no circumstances should you remove the handcuffs of a psychiatric patient just because the patient promises to cooperate or reports "feeling better." The only reason to remove physical restraints after they have been applied would be if the patient's condition deteriorated and the restraints hindered access to the patient. If the patient is complaining of discomfort related to the handcuffs, however, it is important to check and to adjust the tightness of the cuffs if necessary to prevent skin breakdown secondary to pressure from the metal. Overtightened handcuffs can even lead to more serious injuries to the bones and nerves around the wrist.

Narrative

On arrival 70-year-old male patient sitting in recliner is AO × 3 and slightly agitated. Patient complains of a “fullness” in his chest, but denies any dyspnea. Skin is warm and dry with strong and regular radial pulses. PERRLA, glucose—146 mg/dL. While attempting to take patient’s BP, patient became very agitated and jumped to his feet while shooting an imaginary gun. He began shouting repeatedly, “Did I get them?” Law enforcement on scene restrained patient with handcuffs and he was placed on the stretcher in a position of comfort. Patient was loaded into ambulance without incident and law enforcement accompanied EMS in the ambulance due to patient being restrained. Patient calm en route and patient transport was uneventful. Report given to receiving nurse.

End of report

Prep Kit**Ready for Review**

- Behavioral emergencies can present you with great difficulties in patient management. Your major responsibility in these situations is to defuse potentially life-threatening incidents and reduce the impact of the stressful condition without exposing yourself to unnecessary risks.
- Whereas only a small percentage of people with mental health disorders are dangerous to themselves or others, you may be exposed to a higher proportion of violent situations in your daily activities as an AEMT. Warning signs of violence include a history of hostile behavior, rigidity, loud and erratic speech patterns, agitation, and depression.
- A behavioral emergency or psychiatric emergency is any reaction to events that interferes with activities of daily living. A person who is no longer able to respond appropriately to

the environment may be having a more serious psychiatric emergency. Not all behavioral emergencies involve a mental health problem, however: some emergencies are a temporary response to a traumatic event.

- Underlying causes of behavioral emergencies fall into two categories: organic and functional disorders.
- Organic brain syndrome is a temporary or permanent dysfunction of the brain caused by a disturbance in the physical or physiologic functioning of brain tissue.
- Altered mental status is a change in the way a person thinks or behaves, and is an indicator of central nervous system disease.
- A person's environment includes both psychosocial and sociocultural influences on behavior; when these influences cause stress, they may precipitate a behavioral crisis. Other organic causes of behavioral emergencies may include injury or illness and substance use.
- A functional disorder is one in which the etiology cannot be traced to an obvious change in the actual structure or physiology of the brain itself.
- Psychiatric signs and symptoms can affect the following areas: consciousness, motor activity, speech, thinking, mood and affect, memory, orientation, perception, and intelligence.
- Violent patients make up only a small percentage of those experiencing behavioral or psychiatric crises, but it is important to assess for risk factors for such a patient. History, posture, the scene, vocal activity, and physical activity can provide clues as to the likelihood of the patient becoming violent.
- Assessing a person who may be having a behavioral crisis involves observing the person, talking with the person, and talking with friends, family members, and witnesses to the person's behavior. Look for indications that the person's thoughts, feelings, and reactions are inappropriate for the circumstances. Remember to always assess the ABCDEs (Airway, Breathing, Circulation, Disability, and Exposure).
- Consider contributing factors in four areas: central nervous system dysfunction, environmental factors or clues, drug or alcohol use, and psychogenic circumstances such as the death of a loved one or other major interruption of normal life.
- Look for organic causes of a behavioral emergency. Measure vital signs, examine the patient's skin, inspect for evidence of trauma, check the pupils, note unusual odors, and examine the extremities.
- In providing emergency medical care for a patient experiencing a behavioral emergency, be direct, honest, and calm; have a definitive plan of action; stay with the patient at all times, but do not get too close; and express interest in the patient's story, but do not judge the behavior. Always treat patients with respect.
- Psychosis is a state of delusion in which the person is out of touch with reality. Patients with psychosis may be belligerent and angry, or silent and withdrawn. The usual methods of reasoning with a patient are unlikely to be effective with psychotic individuals, so be sure to learn the guidelines in caring for such patients, including being calm, direct, straightforward, and nonconfrontational.
- The threat of suicide requires immediate intervention. Depression is the most significant risk factor for suicide, but other risk factors include personal or family history of suicide attempts, chronic debilitating illness, financial setback, and severe mental illness. Be aware that the patient considering suicide may be homicidal as well.
- You may encounter patients with agitated delirium. This impairment of cognitive function can present with disorientation, hallucinations, or delusions and is characterized by restless and irregular physical activity. One of the most important factors to consider when caring for these patients is your personal safety. Use careful interviewing techniques and refrain from upsetting the patient further.
- In mood disorders, changes in the patient's affect are accompanied by other symptoms, and the net effect is to cause a major disturbance in the person's ability to function. People experiencing mania typically have abnormally exaggerated happiness, joy, or euphoria with hyperactivity and insomnia. In contrast, patients with depression are often readily identified by a sad expression, bouts of crying, and

listless or apathetic behavior; they express feelings of worthlessness, guilt, and pessimism.

- Several types of anxiety disorders, including generalized anxiety disorder, phobias, and panic disorder, are likely to elicit a call for an ambulance or affect the delivery of prehospital care. Panic attacks may mimic a range of physical disorders in their presentation; given the possibility of misdiagnosis, any patient experiencing a panic attack, especially a first panic attack, should be fully evaluated in the hospital.
- As an AEMT, you have limited legal authority to require a patient to undergo emergency medical care in the absence of a life-threatening emergency. Most states have provisions allowing law enforcement personnel to place mentally impaired people in custody so that such care can be provided. You should always involve law enforcement personnel anytime you are called to assist a patient with a severe behavioral or psychiatric crisis.
- Always consult medical control and contact law enforcement for help before restraining a patient. If the patient poses an immediate threat, leave the area until law enforcement secures the scene. If restraints are required, use the minimum force necessary. Assess the airway and circulation frequently while the patient is restrained, and maintain a constant dialogue with the patient throughout the restraining process.
- Symptoms of posttraumatic stress disorder (PTSD) include feelings of helplessness, anxiety, anger, and fear. In addition, people with PTSD can relive the traumatic event through intrusive thoughts, nightmares, or flashbacks.
- The returning combat veteran is a patient who will require a unique level of understanding, compassion, and specialized attention. Take the time to establish the history of this patient and listen to the patient's concerns; approach the individual with sensitivity and respect.

Vital Vocabulary

activities of daily living (ADLs) The basic activities a person usually accomplishes during a normal day, such as eating, dressing, and washing.

affect The outward expression of a person's inner feelings (happy, sad, angry, fearful, withdrawn).

agitated delirium An acute confrontational state characterized by global impairment of thinking, perception, judgment, and memory; also called excited delirium or exhaustive mania.

agoraphobia Literally, "fear of the marketplace"; fear of entering a public place from which escape may be impeded.

altered mental status Any deviation from alert and oriented to person, place, time, and event, or any deviation from a patient's normal baseline mental status; may signal disease in the central nervous system or other contributing factors.

anxiety disorders Mental disorders in which the dominant mood is fear and apprehension.

behavior How a person functions or acts in response to the environment.

behavioral crisis The point at which a person's reactions to events interfere with activities

of daily living; a behavioral crisis becomes a psychiatric emergency when it causes a major life interruption, such as attempted suicide.

bipolar mood disorder A disorder in which a person alternates between mania and depression.

circumstantial thinking A situation in which the patient includes many irrelevant details in an account of things.

compulsions Repetitive actions carried out to relieve the anxiety of obsessive thoughts.

confabulation The invention of experiences to cover gaps in memory, seen in patients with certain organic brain syndromes.

delusions Fixed beliefs that are not shared by others of a person's culture or background and that cannot be changed by reasonable argument; false beliefs.

dementia The slow onset of progressive disorientation, shortened attention span, and loss of cognitive function.

depression A mental health disorder characterized by a persistent mood of sadness, despair, and discouragement.

disorganization A condition in which a person is characterized by uncontrolled and disconnected thought, is usually incoherent or rambling in speech, and may or may not be oriented to person and place.

disorientation A condition in which a person may be confused about their identity, location, and time of day; one of the ways in which various conditions such as schizophrenia or organic brain syndrome may present.

echolalia Meaningless echoing of the interviewer's words by the patient.

flat affect The absence of emotion; appearing to feel no emotion at all.

flight of ideas Accelerated thinking in which the mind skips very rapidly from one thought to the next.

functional disorder A disorder in which there is no known physiologic reason for the abnormal functioning of an organ or organ system.

generalized anxiety disorder (GAD) A disorder in which a person worries about everything for no particular reason, or the worrying is unproductive and the person cannot decide what to do about an upcoming situation.

hallucinations Sense perceptions not founded on objective reality; false perceptions.

inappropriate affect Emotion that is out of synch with the situation (for example, wearing a waxy smile while discussing a parent's death).

loosening of associations A situation in which the logical connection between one idea and the next becomes obscure, at least to the listener.

mania A mental disorder characterized by abnormally exaggerated happiness, joy, or euphoria with hyperactivity, insomnia, and grandiose ideas.

mental disorder An illness with psychological or behavioral symptoms and/or impairment in functioning, caused by a social, psychological, genetic, physical, chemical, or biologic disturbance; may also be referred to as a psychiatric disorder.

mood disorders Disorders in which the disturbance of mood is accompanied by full or partial manic or depressive syndrome.

mutism The absence of speech.

neologisms Invented words that have meaning only to their inventor.

neurotic disorders A collection of mental disorders without psychotic symptoms and lacking the intense psychopathology of other mood disorders; includes anxiety disorders, phobias, and panic disorder.

organic brain syndrome Temporary or permanent dysfunction of the brain, caused by a disturbance in the physical or physiologic functioning of brain tissue.

panic disorder A disorder characterized by sudden, usually unexpected, and overwhelming feelings of fear and dread, accompanied by a variety of other symptoms produced by a massive activation of the autonomic nervous system.

perseveration Repeating the same idea over and over again.

phobias Obsessive, irrational fears of specific things or situations, such as fear of heights, fear of open places, fear of confined spaces, or fear of certain animals.

posttraumatic stress disorder (PTSD) A delayed stress reaction to a prior incident, characterized by the reliving of the stress and nightmares of the original situation. Often the result of one or more unresolved issues concerning the incident, and may relate to an incident that involved physical harm or the threat of physical harm.

pressure of speech Speech in which words seem to tumble out under immense emotional pressure.

psychogenic A symptom or illness that is caused by mental factors as opposed to physical ones.

psychosis A mental disorder characterized by the loss of contact with reality.

schizophrenia A complex, difficult-to-identify mental disorder with typical onset occurring during early adulthood. Dysfunctional symptoms typically become more prominent over time and include delusions, hallucinations, apathy, mutism, flat affect, a lack of interest in pleasure, erratic speech, emotional responses, and motor behavior.

simple phobia A fear that is focused on one class of objects (eg, mice, spiders, dogs) or situations (eg, high places, darkness, flying).

stereotyped movements Repetitive movements that do not appear to serve any purpose.

tangential thinking Leaving the current topic in midconversation to talk about something else, inhibiting interpersonal communication.

thought broadcasting The belief that thoughts are broadcast aloud and can be heard by others.

thought insertion The belief that thoughts are being thrust into one's mind by another person.

thought withdrawal The belief that thoughts are being removed from one's mind.

Chapter 25

Gynecologic Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Gynecology

Recognition and management of shock associated with

- Vaginal bleeding (p 1228)

Anatomy, physiology, assessment findings, and management of

- Vaginal bleeding (pp 1220–1222, 1228)
- Sexual assault (to include appropriate emotional support) (pp 1222, 1228–1231)
- Infections (pp 1214–1220)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the female reproductive system. (pp 1214–1216)
2. Describe abnormalities associated with the menstrual cycle, including premenstrual syndrome, mittelschmerz, and amenorrhea. (p 1216)
3. Discuss the pathophysiology of gynecologic emergencies, including pelvic inflammatory disease, sexually transmitted infections, vaginal yeast infections, ruptured ovarian cyst, ectopic pregnancy, vaginal bleeding, endometritis, endometriosis, postpartum eclampsia, and sexual assault. (pp 1216–1222)
4. Explain the assessment process for patients with gynecologic emergencies. (p 1222)
5. Discuss the importance of history taking when assessing a patient with a gynecologic emergency. (pp 1222–1226)
6. Discuss the general management of a patient with a gynecologic emergency. (pp 1227–1230)
7. Discuss assessment and management of specific gynecologic emergencies, including pelvic inflammatory disease, ruptured ovarian cyst, ectopic pregnancy, and vaginal bleeding. (pp 1227–1228)
8. Discuss special considerations in the assessment and management of victims of sexual assault, including those related to maintaining patient confidentiality and preserving evidence of the crime. (pp 1228–1231)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

Occasionally, girls, women in their childbearing years, and older adult women will have major gynecologic emergencies requiring urgent medical care. These emergencies include excessive bleeding and soft-tissue injuries to the external genitalia. The genitalia have a rich nerve supply; thus, soft-tissue injuries can be very painful. Some gynecologic conditions can be life threatening without prompt intervention. The reproductive system is extremely vascular, and the potential for bleeding is great. You may be called to care for patients with exacerbations or conditions related to sexually transmitted infections (STIs). Also, vaginal discharge (nonbleeding) is a common problem, though not necessarily a true emergency.

This chapter will help you learn how to determine whether a life-threatening emergency exists, which prehospital interventions are required, and if transport is needed. Finally, the chapter discusses gynecologic emergencies unrelated to childbirth.

Words of Wisdom

Although this chapter will discuss gynecologic conditions as pertaining to female patients, providers should be mindful that a patient who does not identify as female can have gynecologic issues. The AEMT must consider conditions relating to the female reproductive system regardless of the patient's apparent gender.

Anatomy and Physiology Review

Anatomy Review

The female reproductive organs include the external female genitalia, uterus, vagina, fallopian tubes, ovaries, and the perineum. The **ovaries** are almond-shaped organs that lie on each side of the upper pelvic cavity (**FIGURE 25-1**). The two functions of the ovaries are to produce ova (mature **oocytes**, or female sex cells; singular, ovum) and the hormones estrogen and progesterone. These hormones are secreted by the corpus luteum, a small, yellow, endocrine structure that develops within a ruptured ovarian follicle (sac), and are responsible for development and maintenance of secondary sexual characteristics, preparation of the uterus for pregnancy, and development of the mammary glands. The **fallopian tubes**, or uterine tubes, are tubes or ducts that extend from the uterus and terminate near the ovary on each side. Their purpose is to carry an ovum from the ovary to the uterus and spermatozoa from the uterus toward the ovary.

The **uterus**, or womb, is the muscular organ where the fertilized egg implants and grows. It is responsible for contractions during labor and ultimately helps push the infant through the birth canal. The uterus is made up of the **fundus**, the uppermost part of the uterus, farthest from the cervical opening; the body, the principal mass of the uterus; the uterine cavity, the space within the uterus; the **endometrium**, the inner layer of the uterine wall; and the **myometrium**, the muscular wall of the uterus.

YOU are the Provider

Part 1

You are requested by law enforcement at a residential dwelling for a 19-year-old woman who reports she was sexually assaulted. On arrival, you find a scared-looking patient who is crying. She states she was sexually assaulted by an unknown assailant who broke into her home, and that she just wants to bathe because she feels "dirty." She is also concerned that the attacker did not use a condom.

1. Should this patient be encouraged to bathe?
2. What are the possible medical impacts of a sexual assault on this patient?

FIGURE 25-1 Front and side views of the female reproductive system.

© Jones & Bartlett Learning.

The **vagina** is the outermost cavity of a woman's reproductive system and forms the lower part of the birth canal. It is about 3 to 5 inches (8 to 12 cm) long, begins at the **cervix** (the neck of the uterus), and ends as an external opening of the body. Essentially, the vagina completes the passageway from the uterus to the outside world for the delivering infant. The cervical canal is the passageway from the uterus to the opening into the vagina.

The external female genitalia, or **vulva**, includes the **mons pubis**, the pad of fatty tissue and coarse skin that lies over the symphysis pubis; the **labia majora**, the outer lip-shaped structure; the **labia minora**, the inner lip-shaped structure; the **clitoris**, the small erectile body partially hidden by the labia minora and covered by the **prepuce** or foreskin; the **vestibule**, the small space at the beginning of the vagina, and its glands; the opening of the **urethra**, the canal for the discharge of urine extending from the urinary bladder to the outside of the body; and the **vaginal orifice**, the opening of the vagina. The vaginal orifice is protected by the **hymen**. This membrane forms a border around the vaginal orifice, partially enclosing it. Contrary to popular belief, the presence or absence of the hymen does not denote virginity. Pregnancy has occurred with the hymen intact. The **perineum**, or pelvic floor, lies

between the vulva and the **anus** (the outlet of the rectum) (**FIGURE 25-2**).

Physiology Review

Each month, as the level of hormones increases in the female, certain characteristic changes take place. The hormones stimulate the development of the eggs in the ovaries and cause the endometrium of the uterus to thicken in anticipation of implantation of a fertilized egg. If an egg is fertilized and implants in the uterus, menses is suspended until such time as the pregnancy ends. If no fertilized egg implants, **menstruation** begins; menstruation is the cyclic shedding of the uterine lining that occurs approximately every 28 days. A typical cycle lasts 4 to 6 days, with blood loss of approximately 1 to 2 oz (25 to 60 mL). The initial onset of menstruation, known as **menarche**, occurs during puberty. **Menopause** is the cessation of menstruation and ovarian function. It generally occurs between the ages of 45 and 55 years.

Many conditions are associated with the menstrual cycle and may be encountered by advanced emergency medical technicians (AEMTs) caring for premenopausal women. Note, however, that these conditions are not necessarily emergencies.

FIGURE 25-2 The external genitalia of the female reproductive system.

© Jones & Bartlett Learning.

Premenstrual syndrome (PMS) is a cluster of troubling symptoms that normally occurs 7 to 14 days before the onset of the menstrual flow and then generally subsides once the flow begins. PMS affects approximately 20% to 30% of all premenopausal women, with one meta-analysis showing worldwide prevalence to be more than 45%,¹ and may be significantly debilitating. Stress, diet, alcohol consumption, and prescription or nonprescription drug use may exacerbate PMS symptoms. In addition, some women may experience reactive hypoglycemia, resulting in increased fatigue. This may be a strong clue as to what is troubling the patient, especially if the history elicits a recent intense craving for sweets or decreased alcohol tolerance. Prehospital treatment is predominantly supportive. Supportive field treatment may include administering oral or intravenous (IV) glucose, if blood glucose levels support the need, or administering a small dose of analgesics or anxiolytics to reduce patient anxiety.

Some women may experience abdominal pain and cramping in the 2 weeks before the beginning of menses. This pain and its accompanying symptoms result from the ovulatory process and are collectively called *mittelschmerz* (pronounced “MITT-ul-shmurz”; German for “middle pain”). *Mittelschmerz*, which may start at any time during ovulation (midcycle), affects approximately 20% of women.² In most cases, the pain is not severe; it may last only a few minutes or as long as 48 hours (average, 6 to 8 hours). Signs and symptoms include sharp, cramping pain in the lower abdomen, often localized to one side, beginning midcycle, with a history of similar pain episodes during previous

periods. The pain may also be reported as “switching sides” from month to month. Some women report feeling nauseated or experiencing minor blood spotting. The condition itself is not serious, and the pain can often be relieved by over-the-counter analgesics. Any persistent pain or any abnormal symptoms are cause for concern and should be evaluated by a physician.

Amenorrhea is the absence or cessation of menses. This condition may be caused by several factors, but the most common cause is pregnancy. Exercise-induced amenorrhea is common in female athletes, particularly those who participate in physically intense sports. Amenorrhea may occur when a woman's body fat drops below a certain percentage. Amenorrhea can also be caused by emotional problems or extreme stress. In adolescents or young adults, the condition may have its origin in an eating disorder such as anorexia nervosa or bulimia; in this case, it is a symptom of the patient's malnutrition and emotional state.

Pathophysiology

Disorders in the female reproductive system can lead to gynecologic emergencies. These disorders include acute or chronic infection, hemorrhage, rupture of a cyst, and rupture of an ectopic pregnancy. The pathophysiology of these emergencies is discussed in this section. Specific assessment and management are discussed later in this chapter.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an acute or chronic infection of the upper female reproductive

organs. Disease-causing organisms enter the vagina during sexual activity and migrate through the opening of the cervix and into the uterine cavity. The infection may then expand to the fallopian tubes, eventually involving the ovaries.

The chief symptoms of PID are pelvic pain and fever. Complications may include sepsis, abscess formation, generalized peritonitis, and infertility. Scarring may cause tubal infertility and increase the risk of ectopic pregnancy. Involvement of the ovaries may result in the development of a life-threatening abscess. Risk factors associated with PID include having multiple sex partners and/or a partner who has had sex with multiple people, having an untreated STI, having a past history of PID, being sexually active, being younger than 26 years, and douching.

Sexually Transmitted Infections

STIs can lead to more serious conditions. For example, PID is typically a secondary infection, with the primary infection being an STI—often chlamydia or gonorrhea. STIs are reviewed briefly here, except for infection with human immunodeficiency virus (HIV). Treatment of a patient with an STI-related emergency typically involves placing the patient in a position of comfort and providing supportive care. HIV is discussed in greater detail in Chapter 16, *Medical Overview*.

Bacterial vaginosis is the most common vaginal infection in women age 15 to 44.³ In this infection, normal bacteria in the vagina are replaced by an overgrowth of other bacterial forms. Symptoms may include itching, burning, or pain and may be accompanied by a “fishy,” foul-smelling discharge. Pregnant women with bacterial vaginosis may have premature babies or babies born with low birth weight. If it is left untreated, then bacterial vaginosis can lead to more serious infections or result in PID. It is treated with metronidazole, an antibiotic. If the patient consumes alcohol while taking this medication, then severe nausea and vomiting may develop.

Chancroid is caused by the bacterium *Haemophilus ducreyi*. This highly contagious yet curable disease causes painful sores (ulcers), usually of the genitals. Swollen, painful lymph glands or inguinal buboes in the groin area may be present as well. Women may be asymptomatic and, therefore, unaware they have the disease.

Chlamydia is caused by the bacterium *Chlamydia trachomatis*. It is currently the most commonly reported STI in the United States.⁴ Although the symptoms of chlamydia are usually mild or absent, some women may report lower abdominal pain, low back pain, nausea, fever, pain during sexual intercourse, and/or bleeding between menstrual periods. Chlamydial infection of the cervix can spread to the rectum, leading to rectal pain, discharge, or bleeding. If it is left untreated, then the disease can progress to PID. In rare cases, chlamydia causes arthritis that may be accompanied by skin lesions and inflammation of the eye and urethra (Reiter syndrome).

Cytomegalovirus (CMV) is a member of the herpesvirus family. This common viral infection has no known cure, and the virus can remain dormant in the body for years. In its active stages, CMV infection may produce symptoms including prolonged high fever, chills, headache, malaise, extreme fatigue, and an enlarged spleen. People with an increased risk for active infection and more serious complications (such as fever, pneumonia, liver infection, and anemia) include people with immune disorders, those receiving chemotherapy, and pregnant women. Newborns who acquire CMV are susceptible to lung conditions, blood conditions, liver conditions, swollen glands, rash, and poor weight gain.

Special Populations

Your differential diagnosis should include STIs even if your patient is elderly. Older adults remain sexually active into their 70s and often later. The incidence of STIs is increasing in patients older than 65 years.

Genital herpes is an infection of the genitals, buttocks, or anal area caused by herpes simplex virus, type 1 or type 2. Type 1, which is the most common form, infects the mouth and lips, causing cold sores or “fever” blisters; it may also produce sores on the genitals. Type 2, the more serious infection, can affect the mouth as well, but is more commonly known as the primary cause of genital herpes. Genital herpes infection is more prevalent in women than in men.⁵

In an active herpes infection (called an outbreak), symptoms generally appear within 2 weeks

of primary infection and can last for several weeks. Symptoms may include tingling or sores near the area where the virus has entered the body, such as on the genital or rectal area, on the buttocks or thighs, or on other parts of the body where the virus has entered through broken skin. In women, the sores may occur inside the vagina, on the cervix, or in the urinary passage. Small red bumps appear first, develop into small blisters, and finally become itchy, painful sores that might develop a crust and heal without leaving a scar. Other symptoms that may accompany the first outbreak, and possibly subsequent outbreaks, include fever, muscle aches and pains, headache, dysuria, vaginal discharge, and swollen glands in the groin area.

Gonorrhea is caused by *Neisseria gonorrhoeae*, a bacterium that can grow and multiply rapidly in the warm, moist areas of the reproductive tract, including the cervix, uterus, and fallopian tubes in women and in the urethra in women and men. The bacterium can also grow in the mouth, throat, eyes, and anus. Symptoms, which are generally more severe in men than in women,⁶ appear approximately 2 to 10 days after exposure. Women may be infected with gonorrhea for months but not have any symptoms, or only mild ones, until the infection has spread to other parts of the reproductive system. When symptoms do appear in women, they generally present as dysuria (painful urination), with associated burning or itching; a yellow or bloody vaginal discharge, usually with a foul odor; and occult blood associated with vaginal intercourse. More severe infections may present with cramping and abdominal pain, nausea and vomiting, and bleeding between menstrual periods; these symptoms indicate that the infection has progressed to PID. Rectal infections generally present with anal discharge and itching and occasional painful bowel movements with fecal blood spotting. Infection of the throat (for which oral sex is the introducing factor) is called gonococcal pharyngitis. Its symptoms are usually mild, consisting of painful or difficult swallowing, sore throat, swollen lymph glands, and fever. Headache and nasal congestion may also be present. If the infection is not treated, then the bacterium may enter the bloodstream and spread to other parts of the body, including the brain—a condition known as disseminated gonococcemia.

Genital warts (also called condylomata acuminata and venereal warts) are caused by the **human**

papillomavirus (HPV). An estimated 79 million people in the United States are infected with HPV, and 14 million new cases occur every year; one-half of new cases occur in young adults, ages 15 to 24 years.⁷ Some infected people have no symptoms. In others, multiple growths develop in the genital areas—that is, the vagina, vulva, and cervix in women; the penis and scrotum in men; and the rectum in either sex. HPV has been identified as a causative agent in cervical, vulvar, and anal cancers. In pregnant women, warts may develop that become large enough to impede urination or obstruct the birth canal. If the virus is passed to the fetus, then laryngeal papillomatosis (throat warts that block the airway), a potentially life-threatening condition, may develop.

Syphilis is caused by the bacterium *Treponema pallidum*. Because many of its signs and symptoms mimic those of other diseases, syphilis is sometimes called the “great imitator” by clinicians. The disease manifests in three stages: primary, secondary, and tertiary. Transmission occurs through direct contact with open sores, which may arise anywhere on the body, but tend to appear on the genitals, anus, rectum, lips, or mouth. A person with syphilis may remain asymptomatic for years, not realizing that the sores are manifestations of a disease.

Words of Wisdom

Although syphilis manifests in three stages, it involves a total of four stages. Between the secondary stage and the tertiary stage (which is now rare), there is a latent stage when there are no visible signs or symptoms of syphilis. If individuals do not receive treatment, they can continue to have syphilis in their body for years without any signs or symptoms.

The primary stage of syphilis is usually marked by the appearance of a single sore (a chancre), although some people develop multiple sores. The chancre is usually painless and is small, firm, and round. It usually goes away after 3 to 6 weeks, at which point the disease has progressed to the second stage.

The secondary stage of syphilis is characterized by the development of mucous membrane lesions and a rash. The characteristic rash may present on the palms of the hands and the bottoms of the feet

as rough, red or red-brown spots. Alternatively, it may be barely discernible or resemble rashes from other diseases. The rash generally does not itch. Symptoms of secondary syphilis may include fever, swollen lymph glands, sore throat, patchy hair loss, headache, weight loss, muscle ache, and fatigue. Like the chancre of the primary stage, these symptoms will resolve without treatment. Left untreated, the secondary stage invariably leads to tertiary syphilis.

In the tertiary stage of syphilis, internal damage is accumulating. Syphilis attacks the brain, nerves, eyes, heart, blood vessels, liver, bones, and joints, although it can take years for syphilis to progress from the primary stage to the tertiary stage; thus, the damage may not become evident for years. Paralysis, numbness, dementia, gradual blindness, and difficulty coordinating muscle movements are possible physical manifestations and may be serious enough to cause death. Pregnant women with syphilis may have stillborn babies, babies who are born blind, developmentally delayed babies, or babies who die shortly after birth.

Trichomoniasis is caused by a single-celled protozoan parasite, *Trichomonas vaginalis*. This parasite is transmitted through sexual contact, with the vagina being the most common site of infection. The infected person may be asymptomatic or may experience signs and symptoms including a frothy, yellow-green vaginal discharge with a strong odor. The infection may also cause irritation and itching of the female genital area, discomfort during intercourse, dysuria, and lower abdominal pain. When present, symptoms usually appear in women within 5 to 28 days of exposure to *T vaginalis*. If it is left untreated, then the infection can lead to low birth weight or premature birth in pregnant women and increase the patient's susceptibility to HIV infection.

Vaginal Yeast Infections

Vaginal yeast infections are typically caused by the *Candida albicans* fungus. Yeasts are tiny organisms that normally live in small numbers inside the vagina and on the skin. The normal acidic environment of the vagina helps keep yeast from growing. If the vagina becomes less acidic, however, the yeast population may increase dramatically and result in infection. Conditions that may alter the

acidic balance of the vagina, allowing yeast overgrowth, include the use of oral contraceptives, menstruation, pregnancy, diabetes, and some antibiotics. Moisture and irritation of the vagina also seem to encourage yeast growth. Stress from lack of sleep, illness, and poor diet are other contributing factors. Women with immunosuppressive diseases such as HIV infection or diabetes are also at increased risk. Symptoms include itching, burning, soreness in the vagina and around the vulva, and vulvar swelling. Some women may report a thick, white vaginal discharge ("cottage cheese" appearance), pain during sexual intercourse, and burning on urination.

Ruptured Ovarian Cyst

An ovarian cyst is a fluid-filled sac attached to the inside or outside of the ovary. As the cyst enlarges, it can become filled with an enormous amount of fluid. The cyst may need to be removed surgically to relieve pressure or to treat infection. Complications include possible significant internal bleeding; however, this is rare.

Ectopic Pregnancy

Ectopic pregnancy—a pregnancy that develops outside the uterus, most often in a fallopian tube—occurs in nearly 20 of every 1,000 pregnancies.⁸ Vaginal bleeding may be the only sign of an ectopic pregnancy. The leading cause of maternal death during the first trimester is internal hemorrhage into the abdomen following rupture of an ectopic pregnancy.⁸ For this reason, you should consider the possibility of an ectopic pregnancy in women who have missed a menstrual cycle and report sudden stabbing and usually unilateral pain in the lower abdomen. A history of PID, tubal ligation, or previous ectopic pregnancy should heighten your suspicions for a possible ectopic pregnancy. Consider the possibility of an ectopic pregnancy in any female of reproductive age who has abdominal pain.

An ectopic pregnancy occurs when the ovum develops outside the uterus. Numerous causes may affect the normal pathway of the ovum, preventing it from implanting in the uterus. Previous surgical adhesions, PID, a tubal ligation (having the fallopian tubes surgically tied to prevent pregnancy), or an IUD may interfere with the movement of a

fertilized egg. Generally, it is the fallopian tubes that are affected, but on rare occasions, implantation may occur elsewhere in the pelvic cavity. Because the fallopian tubes are extremely narrow, even the slightest growth of the egg will cause symptoms; therefore, ectopic pregnancy is an early first-trimester emergency, typically occurring within the first 6 to 8 weeks of pregnancy.

In ectopic pregnancy, the cells begin to divide and the zygote grows, even though this process occurs without the aid of oxygen or nutrients. Therefore, there is no viable fetus that can be removed and implanted in the uterus. Eventually, the fallopian tube will rupture if the ectopic pregnancy is not caught in time; this rupture can lead to a life-threatening emergency.

Special Populations

Vaginal bleeding in a young girl may be the result of menarche. There is no set age for the beginning or cessation of menstruation. Likewise, unusual signs and symptoms in an older adult patient going through menopause may be an indication of an unexpected pregnancy.

Vaginal Bleeding

Vaginal bleeding can be as simple as a normal menstrual cycle or as extreme as a ruptured uterus. Never assume an emergency call for vaginal hemorrhage is bleeding from normal menstruation.

Bleeding that occurs during the first or second trimester of a known or possible pregnancy might indicate a spontaneous **abortion** or miscarriage, especially if the last menstrual cycle was more than 60 days ago.

Any vaginal bleeding during the third trimester of pregnancy is a serious emergency. **Placenta previa** presents with bright red bleeding, and **abruptio placentae** presents with dark bleeding. However, these color differences can be difficult to discern in the prehospital setting. It may be more helpful to note that patients who have placenta previa tend to have significant bleeding and mild pain, whereas patients with abruptio placentae tend to have little bleeding and moderate to severe abdominal pain. These topics will be addressed further in Chapter 35, *Obstetrics and Neonatal Care*.

Other causes of vaginal bleeding include the following:

- Onset of labor
- Ruptured ectopic pregnancy
- PID and other infections
- Trauma
- Lesions from previous surgeries or disease processes

Vaginal bleeding may result from the following traumatic causes:

- **Straddle injury.** This type of injury occurs when a female falls onto an object, such as the bar of a boy's bicycle, causing trauma to the external genitalia and perineum.
- **Blows to the perineum.** A blow to the perineum may be associated with falls or assault.
- **Blunt force to the lower abdomen from assault or seat belt injuries.** Any blunt force to the lower abdomen has the potential to rupture organs or cause serious injury, such as a lap belt causing injury in a motor vehicle crash or blows to the abdomen during an assault.
- **Foreign bodies inserted into the vagina.** This injury may be self-inflicted or the result of a sexual assault.
- **Abortion attempt.** Trauma occurs when a female uses an object such as a clothes hanger in an attempt to abort her pregnancy. This can cause massive trauma and extensive bleeding.
- **Soft-tissue injury.** Sexual assault and vigorous sexual activity can cause soft-tissue injury. Any or all of the pelvic organs may be affected.

Endometritis

Endometritis is an inflammation or irritation of the endometrium (uterine lining). Women are more likely to have endometritis after having a baby or after a miscarriage. This condition is most commonly caused by an infection, frequently by an STI (gonorrhea and chlamydia, predominantly).

Symptoms of endometritis may include malaise, fever (high or low grade), constipation or uncomfortable bowel movements, vaginal bleeding or discharge (or both), abdominal distention, and lower abdominal or pelvic pain. Abdominal auscultation may reveal decreased bowel sounds, and pain may be elicited by palpation of the abdomen.

Endometritis is treated with antibiotics. Provide reassurance to the patient and transport in a position of comfort. If necessary, then start an IV line and titrate to the patient's vital signs. Left untreated, endometritis may lead to septic shock or cause spontaneous abortion in a pregnant patient. Most patients fully recover after antibiotic treatment.

Endometriosis

Endometriosis is believed to develop in more than 6.5 million women in the United States every year.⁹ This condition can be extremely painful, yet some women may not have any symptoms. It results when endometrial tissue grows outside the uterus, generally on the surface of abdominal and pelvic organs. Organs of the pelvic cavity are the most common locations for the ectopic growths, but endometrial tissue can occasionally be found in the lungs or other parts of the body. Endometriosis is one of the leading causes of infertility in women, with 30% to 50% of infertile women having this condition.¹⁰ Many women do not even realize they have endometriosis until they encounter difficulties trying to get pregnant.

In women who experience symptoms, the most common complaint is pain (sometimes chronic pain), generally localized in the lower back, pelvic, and abdominal regions. Other symptoms include painful intercourse (during and after),

gastrointestinal pain, dysuria and painful bowel movements during the menstrual cycle, fatigue (perhaps leading to misdiagnosis as chronic fatigue syndrome), extremely painful and escalating menstrual cramping, and very heavy menstrual periods. Patients may also experience bleeding between periods or report premenstrual spotting.

Prehospital care for endometriosis is based on the patient's signs and symptoms. If the patient reports severe pain, then provide pain relief with analgesics if allowed in your protocol. Let the patient position herself so she is as comfortable as possible. Use dressings or towels as needed to absorb any significant vaginal bleeding.

Postpartum Eclampsia

You may not think of eclampsia when treating patients with gynecologic emergencies, but after a baby is born, the mother is at risk for eclampsia for several weeks. Postpartum eclampsia usually presents within the first 24 hours after delivery, but may occur as late as 4 weeks following the birth. You may receive a call to care for a woman with seizures and hypertension who has delivered a baby a few weeks earlier. A thorough history is important to determine whether the seizure could be caused by postpartum eclampsia. In such a scenario, paramedic backup is required. Eclampsia is covered in more detail in Chapter 35, *Obstetrics and Neonatal Care*.

YOU are the Provider

Part 2

You explain to the patient that if she were to bathe, she would be removing potential evidence from her body. Therefore, she reluctantly agrees to be transported to the ED for a sexual assault examination.

Recording Time: 1 Minute

Appearance	Visibly upset
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent
Breathing	Normal rate and rhythm
Circulation	Strong radial pulses; skin warm and dry

3. If available, should a female provider accompany the patient in the rear of the ambulance?
4. What kind of care does this patient require en route to the hospital?

Sexual Assault

Unfortunately, sexual assault and rape are all-too-common occurrences in today's society. Although most victims are women, men and children are also victims. Often, there is little you can do beyond providing compassion and transportation to the emergency department (ED). In some cases, the patients will have sustained multiple-system trauma and will also need treatment for shock. This is discussed in more detail later in this chapter.

Patient Assessment

Obtaining an accurate and detailed patient assessment is crucial when dealing with gynecologic emergencies. You may not be able to make a specific diagnosis in the field, but a thorough patient assessment will help determine just how sick the patient is and whether you should initiate life-saving measures. This is especially true when caring for patients with abdominal pain.

Women have many of the same conditions that cause abdominal pain in men—for example, ulcers and appendicitis. In addition, there are numerous gynecologic causes of abdominal pain. An old medical axiom states, “Anyone who neglects to consider a gynecologic cause in a woman of childbearing age who reports abdominal pain will miss the diagnosis at least 50% of the time.” Missing the diagnosis may be fatal for the patient.

Scene Size-up

Every emergency call—including calls involving gynecologic emergencies—begins with a thorough scene size-up. Gynecologic emergencies can be very messy, sometimes involving significant amounts of blood and body fluids contaminated with organisms that can potentially cause communicable diseases. Take standard precautions.

Where and in what position is the patient found? If she is at home, what is the condition of the residence? Is it clean or dirty? Do you see evidence of a fight? Is alcohol or evidence of drug use present? Are there photos of loved ones or is there a noticeable absence of photos? Does the patient live alone or with other people? All information you obtain contributes to your assessment of the patient's overall health and

the safety of the scene. In the case of a crime scene, you may also be required to testify in court regarding the conditions on your arrival. Your documentation needs to be accurate and thorough. Involve law enforcement if any type of assault is suspected. In cases of sexual assault, it is valuable to have a female AEMT provide patient care, so consider calling for one early if you and your partner are men.

Often the mechanism of injury (MOI) or nature of illness (NOI) in patients with gynecologic problems will be understood from the dispatch information, such as in cases of sexual assault. In other patients, the exact nature of the condition will not emerge until you gather patient history information. For example, the patient may present with vague symptoms such as abdominal pain, and you may not be able to determine the exact NOI until you gather more information during the patient history.

Primary Survey

The general impression is an important aspect of all patient assessments. As you approach the patient, you should quickly determine if her condition is stable or unstable. Use this information to help you as you proceed further with the assessment. Use the AVPU (Alert to person, place, and time; responsive to Verbal stimuli; responsive to Pain; Unresponsive) scale to determine the patient's level of consciousness, and immediately assess airway, breathing, circulation, disability, and exposure (ABCDEs).

If the patient has experienced significant blood loss because of vaginal bleeding, she may not demonstrate obvious signs of shock but may still be hypovolemic. If the patient has a weak or rapid pulse or has pale, cool, or diaphoretic skin, then place the patient in a supine position. Cover the patient to keep her warm, and then transport to the nearest appropriate receiving facility for treatment. Most cases of gynecologic emergencies are not life threatening; however, if signs of shock exist because of bleeding, then rapid transport is necessary. The remainder of the assessment can be performed en route to the hospital.

History Taking

Begin by asking about the patient's chief complaint, but realize that some of the questions you must ask

may be considered extremely personal. Be sensitive to the patient's feelings and ensure her privacy and dignity are protected. Gynecologic emergencies can be highly embarrassing for the patient, and many women may be extremely uncomfortable with discussing their sexual history in front of strangers or even close family members. An adolescent girl may want to keep her sexual history from her parents.

When asking patients about sensitive subjects, ensure you do so in a quiet manner away from bystanders. If the patient seems to be emotionally distressed, then assess the cause and degree of distress. This may require moving the patient to the ambulance to remove her from the source of the problem. This is especially true in cases of suspected abuse. Ask only the questions pertinent to your evaluation of her physical status. Your sensitive and caring manner can help you serve as a role model to others.

Gynecologic emergencies often have the same signs and symptoms as emergencies involving other abdominal organs. Assess the patient carefully to determine the nature and extent of the condition. Include the following elements in your assessment:

- SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury)
- Ask about the patient's last menstrual period.
- What, if any, associated symptoms are noted:
 - Fever?
 - Diaphoresis?
 - Syncope?
 - Diarrhea?
 - Constipation?
 - Painful or difficult urination (dysuria)?

The nature and location of pain may also give clues to the origin of the problem. Is the pain localized or diffuse? Is it constant, or does it come and go? Is there any radiation or referred pain? Rebound tenderness? Remember to ask specifically:

- Describe any pain or discomfort.
 - OPQRST-I (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, Interventions prior to EMS arrival)?
 - Abdominal pain?
 - **Dysmenorrhea**—does the patient have painful menstruation?
- Are there any aggravating factors?
 - Ambulation—does it hurt the patient to move?

FIGURE 25-3 Note the position of the patient during your assessment.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

- Dyspareunia—does the patient have pain during sexual intercourse?
- Defecation—does it hurt to pass stool?
- Are there any alleviating factors?
 - Positioning—does the patient feel better when in a different position (**FIGURE 25-3**)?
 - Ceasing activity—does the pain decrease when the patient stops moving?

Other medical conditions may present as an abdominal condition. Cardiac pain, for example, may be misinterpreted as epigastric pain. Other conditions may also exacerbate gynecologic emergencies. Besides obtaining a SAMPLE history, be sure to ask the patient about previous episodes of this type of condition.

- What is the patient's present health?
 - Any preexisting conditions?
 - Any previous surgeries?

Determine whether the patient has a history of gynecologic conditions and whether she has had any infections. If so, did she seek medical treatment? What was the diagnosis? If she thinks she may be having a repeat episode, has she taken any medication or used any over-the-counter treatment?

Ask the patient if she has had any recent surgeries or procedures (eg, abortion, biopsies, dilation and curettage), because these procedures can cause vaginal bleeding. Some office-based procedures can cause bleeding, but the patient may not think of them as surgeries.

Ask about previous pregnancies. How many times has she been pregnant? How many pregnancies have been carried to term, resulting in live birth? Have there been any miscarriages or clinical abortions, and if so, how many?

Words of Wisdom

Suppose your patient is pregnant and has given birth to two children with no miscarriages. This information can be documented on the patient care report as G3, P2, A0. Gravida [G] is the number of pregnancies including the current pregnancy; para [P] is the number of pregnancies carried to term; and abortus [A] represents the number of miscarriages, stillbirths, or surgical abortions.

Ask whether the patient has ever had an ectopic pregnancy. If so, how far along was the pregnancy? Has she ever had a cesarean section? A patient with a history of an obstetric condition tends to be more susceptible to repetitive problems.

If the patient is currently bleeding, then try to estimate the amount of blood loss. What color is the blood? Is it dark, like the normal menstrual flow, or is it bright red? How many pads are soaked per hour? Take any clots or soaked pads along with the patient to the hospital in a plastic bag. How long has the bleeding been going on? Remember that some women will continue to have menstrual cycles even though they are pregnant. The flow tends to be lighter and may be only “spotting.” Therefore, the presence of bleeding does not rule out pregnancy.

Special Populations

Vaginal or urinary bleeding is not common in older adult women who are postmenopausal and is a definite cause for concern. When the patient is an older woman who reports genitourinary bleeding, be sure to take a thorough history, including the use of anticoagulants in her daily medication regimen. Treatment for the most part is strictly supportive unless the bleeding is severe and the patient is exhibiting signs of shock.

If the patient reports any vaginal discharge, then note the color, amount, consistency, and any odor. Is there any irritation or pain associated with

the discharge? Is there any burning or irritation with urination?

Inquire about the use of contraceptives. What type is used? Is the patient consistent with its use?

Ask the patient about a missed or late period. When was the patient’s last menstrual cycle? How long did it last? Was it normal in duration and amount of flow? Also ask the patient about any bleeding between periods (breakthrough bleeding). A patient who has a regular menstrual cycle is more likely to recognize a problem than one who has an irregular cycle. Determine regularity and how this occurrence differs from the usual pattern.

Special Populations

Most teenage girls feel uncomfortable discussing gynecologic emergencies in front of their parents. They may even refuse to seek help to avoid the embarrassment of the situation. Allow them the opportunity to talk privately, and assure them of your discretion (**FIGURE 25-4**). In most cases, a parent will be required to authorize treatment of a minor, but in the case of pregnancy the minor becomes “emancipated” and is legally able to give or refuse consent. STIs are also confidential issues in some areas and do not require parental consent for treatment. Regardless, stress the need for the patient to seek treatment for any gynecologic emergency.

Become familiar with the laws in your area regarding privacy and minors. These laws differ by state, and you should know them before finding yourself in a situation requiring knowledge of them.

FIGURE 25-4 Respect the privacy of teenagers by questioning them away from parents or other bystanders.

Courtesy of Rhonda Hunt.

Consider the possibility of pregnancy in any woman of childbearing age (approximately 12 to 60 years) even if contraception has been used. Also consider the possibility of pregnancy even if the patient denies a history of sexual activity, because this denial may be based on cultural factors or age-related stigma. Is there any breast tenderness? Has the patient noticed a need to urinate frequently without an increased fluid intake? Is there any nausea or vomiting that may be morning sickness? While maintaining the patient's privacy, question the patient to determine whether she is sexually active and whether she has had unprotected sex.

Finally, address any trauma. Determine whether there has been any history of trauma to the reproductive system.

Secondary Assessment

The secondary assessment may be performed on scene, en route to the ED, or, in some instances, not at all. If the patient is critically ill or injured or the transport time is short, then you may not have time to conduct this part of the patient assessment process.

The physical exam is performed in the same manner as the exam for other medical emergencies, with special consideration for the female reproductive system. Approach the patient with a comforting attitude. Protect the patient's modesty by placing a sheet over her and removing only the items of clothing necessary to perform your assessment. Maintain privacy during the exam and while interviewing the patient. Be considerate of the patient's needs and the reason for her discomfort. If the patient has a history of an STI (eg, HIV, genital herpes, gonorrhea), then treat her appropriately and without moral judgment.

Focus your physical exam on the NOI and the patient's chief complaint. Assessment of the external genitalia should be done only when necessary and should be a visual inspection only. If vaginal bleeding is the NOI, then you should visualize the bleeding and ask about its quality and quantity. Use external sanitary pads to control the bleeding, and keep the possibility of hypoperfusion or shock in mind. Always ask if there is pain associated with the vaginal bleeding or discharge. Never insert anything into the vagina to control bleeding, including a tampon.

Vaginal discharge is another condition that should be observed if possible. Make observations about the discharge, and ask the patient about any qualities she noticed and the history of the discharge.

Fever, nausea, and vomiting are common with many medical conditions but should be considered especially significant with gynecologic emergencies. Fever should always be considered a sign of an infectious process. Any report of syncope by the patient, especially if she reports vaginal bleeding, is considered significant. Treat the patient reporting this symptom as being in shock until proven otherwise.

Assess the patient's vital signs. Include any orthostatic changes. Hypotension in a patient with abdominal pain may be a sign of internal bleeding in the absence of external hemorrhage. Tachycardia and changes in respiration might also signal shock. Note the color and amount of any bleeding or discharge. If there is any evidence of clots and/or tissue, then transport the patient to the hospital.

Expose and examine the abdomen to look for any discoloration or swelling. Palpate for any masses, tenderness, guarding, distention, or rebound tenderness. If the patient reports discomfort in a particular area, then always begin your assessment in the quadrant farthest away from the area of pain, and palpate the painful area last.

Use the appropriate monitoring devices, such as pulse oximetry, to track the patient's condition.

Assessment Pearls

- Regardless of the complaint, remember, airway comes first. Ensure adequate oxygenation and control any external bleeding immediately.
- Do not discount age when considering pregnancy. Ask about the last menstrual cycle regardless of age.
- Severe pain in any area should be treated as a medical emergency.
- Be alert for subtle signs of shock. A patient with a ruptured ectopic pregnancy can decompensate quickly from rapid blood loss.
- Be empathetic when dealing with all patients, regardless of their complaint. A judgmental attitude is inappropriate and may result in an uncooperative patient.

Remember that pulse oximetry readings may be inaccurate in certain situations, such as hypovolemia. Also consider using noninvasive blood pressure monitoring to continuously track the patient's blood pressure. Assess the patient's first blood pressure manually with a sphygmomanometer (blood pressure cuff) and stethoscope.

Reassessment

Few interventions can or should be done for a patient with a gynecologic emergency. If a patient has vaginal bleeding, then treat her for hypoperfusion or shock. Keep her warm, place her in a supine position, and provide her with supplemental oxygen even if she is not experiencing difficulty breathing. Then transport to the nearest appropriate receiving facility.

En route to the receiving hospital, reassess vital signs and watch for trending. Recheck your interventions and note any improvement (or decline) in the patient's condition. Pay specific attention to the needs of the patient, and accommodate her desire for conversation or silence. These patients may be particularly emotionally vulnerable. Do not focus on your paperwork; although important, the paperwork can wait until the patient has been delivered to the receiving facility.

Notify staff at the receiving hospital of all relevant information, including the possibility of pregnancy, so a proper response can be prepared. Carefully document the patient's condition, her chief complaint, the scene, any findings including vital signs, and all interventions, especially in cases of sexual assault.

Emergency Medical Care

Whenever you care for patients with gynecologic emergencies, you must maintain the patient's privacy and modesty as much as possible. Gain the patient's confidence by communicating appropriately and answering questions honestly. Provide psychological support en route to the hospital. Remain calm, and provide reassuring, gentle care. Call for paramedic backup if needed.

Excessive internal vaginal bleeding can have many causes and can possibly lead to hypoperfusion

or shock. Determining the cause of the bleeding should be less important than treating for shock and transporting the patient to an appropriate facility. Use sanitary pads on the external genitalia to absorb the blood, and discourage the use of tampons. Document the number of sanitary pads that were saturated with blood to help the physician estimate blood loss.

If the patient is demonstrating signs of shock or has excessive vaginal bleeding, then place her in a supine position and keep her warm. Establish at least one IV line using a large-bore IV catheter in a large vein. Administer a 20-mL/kg bolus of an isotonic crystalloid solution such as normal saline or lactated Ringer solution if the patient is showing signs of hypovolemia and adjust the flow rate to maintain radial pulses. Consider establishing a second IV line.

If the patient is not demonstrating signs of shock, then place her in a position of comfort based on her presentation. Some patients with abdominal pain find it more comfortable to lie in a lateral recumbent position. Place the patient on the left side so that she will be facing you instead of the wall of the ambulance. Some patients prefer a knee-chest position, whereas others prefer the hips raised and the knees bent.

Treat any external lacerations, abrasions, and tears with sterile compresses, using local pressure to control bleeding and a diaper-type bandage to hold the dressings in place. Leave any foreign bodies in place after stabilizing them with bandages. Under no circumstances should you pack or place dressings inside the vagina. Continue to assess the patient while transporting her to the receiving facility. Contusions and other blunt trauma will require careful in-hospital evaluation.

Consider the possibility of pregnancy, and be prepared for a possible miscarriage. Anticipate the presence of an ectopic pregnancy on the basis of signs and symptoms. If an ectopic pregnancy is suspected, then be alert for possible hypovolemic shock in the event of rupture. Evaluation by a physician is necessary. Transport the patient to the closest appropriate facility. This may include one with a labor and delivery department or a trauma center with surgical intervention capabilities. Consider emergency transport based on the patient's presentation.

Assessment and Management of Specific Emergencies

The pathophysiology of gynecologic emergencies was discussed earlier in this chapter. This section discusses assessment and management of specific gynecologic emergencies.

Pelvic Inflammatory Disease

Assessment findings of PID include lower abdominal pain, fever, vaginal discharge, and dyspareunia (pain during sexual intercourse). The patient will generally walk doubled-over and guard the abdomen, and she may present with a distinctive gait that appears as a shuffle to avoid excessive movement of the abdominal muscles. The patient will also appear ill.

Care includes placing the patient in a position of comfort and providing transport to an appropriate facility.

Ruptured Ovarian Cyst

When an ovarian cyst ruptures, a sudden onset of severe lower abdominal pain may be noted. Most patients have unilateral pain, on the affected side, that may radiate from the abdomen to the back.

Rupture of the cyst may result in some vaginal bleeding. Management of vaginal bleeding is discussed later in this section.

Ectopic Pregnancy

A patient with an ectopic pregnancy usually presents with signs of hypovolemic shock. The patient may report severe abdominal pain that radiates to the back. Vaginal bleeding may be absent or minimal. The patient will generally report amenorrhea even if she does not know she is pregnant. If rupture occurs, then bleeding may be excessive. Expect signs and symptoms of shock. Ask the patient about additional relevant history. If the patient has previously undergone abdominal surgery, then surgical adhesions may be present. Ask whether she has experienced PID or a tubal ligation, uses an IUD, or has previously had an ectopic pregnancy.

Monitor the patient for impending shock, including orthostatic vital signs. Note the presence and volume of vaginal blood. A ruptured ectopic pregnancy is a true medical emergency. In addition to the general management, if signs and symptoms of shock are present, establish a second IV line and treat appropriately. Transport the patient rapidly to the closest appropriate facility.

YOU are the Provider

Part 3

As you transport the patient to the hospital, the patient states, "I don't know what I did to deserve this." She further states she just wants to be left alone.

Recording Time: 15 Minutes

Respirations	22 breaths/min, crying
Pulse	Strong and regular, 120 beats/min
Skin	Warm and dry
Blood pressure	102/68 mm Hg
Oxygen saturation (SpO₂)	99%
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- Does this type of call require any special documentation?
- If you are able to preserve the patient's clothing in a bag for evidence, then in what type of bag should you place the clothing?

Vaginal Bleeding

A patient may experience menorrhagia, or heavy vaginal bleeding. Carefully ask the patient about the amount of bleeding, and treat her appropriately based on presenting signs and symptoms.

Always assume that any bleeding during the first or second trimester of a known or possible pregnancy might indicate a spontaneous abortion or miscarriage, especially if the last menstrual cycle was more than 60 days ago. Ask the patient about any previous similar events. Are there any large clots or pieces of tissue? If so, then take the patient to the ED for further evaluation. This experience can be a very tragic time for the patient, so emotional support is extremely important.

Any vaginal bleeding during the third trimester of pregnancy is a serious emergency and could be the result of placenta previa or abruptio placentae. A physician should evaluate any vaginal bleeding differing in amount and duration from the normal menstrual cycle. The reproductive organs are very vascular, and any bleeding may be life threatening. Hemorrhage can quickly lead to hypovolemic shock and death. Bleeding related to obstetric emergencies is covered in detail in Chapter 35, *Obstetrics and Neonatal Care*.

When you are assessing a patient who has vaginal bleeding, ensure that you inquire about the onset of symptoms. Does the onset coincide with the normal menstrual cycle? Was there any trauma involved? Is there any chance of pregnancy? Is there a history of bleeding? Check for signs of impending shock, including orthostatic vital signs. Note the presence and volume of bleeding, and remember to take any tissue or clots to the hospital for evaluation.

Patients who have experienced abdominal trauma generally present with a variety of signs and symptoms that can include severe bleeding, pain, and hypovolemic shock (**FIGURE 25-5**). Specific assessment findings are consistent with severe internal injuries. Management should be based on patient presentation.

Sexual Assault

Sexual assault can take many forms, but the most common is **rape**. In the United States, 21% of women will be raped during their lives (though only 16% to 19% of victims file a crime report),¹¹ and one

FIGURE 25-5 A patient with gynecologic trauma should be transported lying down.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

of every four will be sexually molested, often before the age of 12 years.¹²

Because rape is a crime, you can generally expect police involvement early in the situation. In many cases, emergency medical services (EMS) may be called by the police. Police officers generally have rudimentary medical training, with many states requiring at least basic training at the first responder level. Nevertheless, primary training for police officers focuses on investigation, not patient care.

Words of Wisdom

Sexual violence does not happen only to females. Younger individuals are at the greatest risk for sexual assault, with most assault victims being 12 to 34 years old. Although girls and women are most commonly the victims, boys and men are also victims. One of every 10 rape victims is male. The transgender population is also at higher risk.

Long-term effects of sexual violence include posttraumatic stress disorder, severe distress (emotional and physical), and suicidal ideations and/or attempts. Sexual assault victims are also more likely to use drugs compared with the general public. As a result, relationships with family, coworkers, and friends often suffer, and victims experience increasing problems at work, home, and school.¹³

A rape victim has just experienced a purposeful “major vehicle crash” of the mind and body. The act was most likely perpetrated by someone the patient

knew and trusted. The last thing the patient wants to do is give a concise, detailed report of what was just experienced, and attempting to elicit information in this manner will most likely cause the patient to “shut down.” Whenever possible, a female rape victim should be given the option of being treated by a female AEMT because the patient may be experiencing ambivalent feelings toward men in general; these feelings will hinder assessment and the patient’s well-being.

It is the job of law enforcement officers to solve the crime, arrest the perpetrator, and ensure justice is served. The job of AEMTs is to manage the medical aspects of the case and to act as the patient’s advocate. In this capacity, it is important for you to focus on several key issues (TABLE 25-1).

AEMTs called on to treat a victim of sexual assault, molestation, or actual or alleged rape face many complex issues, ranging from the obvious medical ones to the serious psychological and legal issues. Specifically, you may be the first person the victim has contact with after the encounter, and how the situation is managed from the first contact throughout treatment and transport may have lasting effects for the patient and you. Professionalism, tact, kindness, and sensitivity are of paramount importance.

Street Smarts

During the assessment, explain to the patient what you are about to do and why. This will help gain the patient’s trust and confidence.

Limit any physical exam to a brief survey for life-threatening injuries. Expose and examine the vaginal area only if there is evidence of bleeding that needs to be treated. Do everything possible to protect the patient’s privacy and give some sense of control back to the patient. Examine and interview the patient with a minimum of people present, moving her to the ambulance if necessary to ensure privacy.

The first issue is the medical treatment of the patient. Is she physically injured? Are any life-threatening injuries present? Does the patient complain of any pain?

The second issue is your psychological care of the patient. Do not cross-examine her or attempt to elicit information for the benefit of the police. These issues will be handled later in the ED. Do not pass judgment on the patient, and protect her from the judgment of others on the scene. It does

TABLE 25-1 Treatment Principles for Sexual Assault

In addition to the usual treatment principles that apply to all patients, follow these special steps with patients who have been sexually assaulted:

- 1. Document the patient’s history, assessment, treatment, and response to treatment in detail because you may have to appear in court as long as 2 or 3 years later. Do not speculate. Record only the facts.
- 2. Complete the SAMPLE history objectively.
- 3. Follow any crime scene policy established by your system to protect the scene and any potential evidence for police, particularly that for evidence collection. If the patient will tolerate being wrapped in a sterile burn sheet, this may help investigators to find any hair, fluid, or fiber from the alleged offender.
- 4. Do not examine the genitalia unless there is major bleeding. If an object has been inserted into the vagina or rectum, then do not attempt to remove it.
- 5. To reduce the patient’s anxiety, ensure the AEMT is the same gender as the patient, whenever possible.
- 6. Discourage the patient from bathing, voiding, or cleaning any wounds until the hospital staff has completed an assessment. Handle the patient’s clothes as little as possible, placing articles and any other evidence in paper bags. If the patient insists on urinating, then ask the patient to do so in a sterile urine container (if available). Also, deposit the toilet paper in a paper bag. Seal and label the bag for the police. This can be critical evidence.
- 7. If possible, transport the patient to a hospital with specialized staff, such as sexual assault nurse examiners (SANEs), who can fully evaluate these patients, perform medical and forensic examinations, and provide all aspects of medical and supportive care for these patients.

Abbreviations: AEMT, advanced emergency medical technician; SAMPLE, Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury

not matter how the patient is dressed, what her local reputation is, where she was, or what she was doing when the assault occurred. The concept of a woman “deserving” to be raped is just as ludicrous as you “deserving” to be assaulted for wearing the colors of a rival sports team. A crime has been committed, and you need to remain cognizant of that fact. Many women report feeling as though they have been “raped again” when subjected to interrogation, criticism, or incredulity.

Remember, you are at a crime scene. Although your job is to treat the *medical* aspects of the incident and not collect evidence, you still have a responsibility to *preserve* evidence. Do not cut through any clothing or throw away anything from the scene. Place bloodstained articles in separate paper (not plastic) bags. Obtain evidentiary bags from the police if necessary. Paper bags allow wet items to dry naturally, whereas plastic allows mold to grow and may destroy biologic evidence.

It may also be necessary to gently persuade the patient to *not* clean up. This will be a natural desire on the part of the patient, stemming from the desire to “wash away” the humiliation and embarrassment of the assault. Valuable evidence can be destroyed in this process. The patient also needs to be discouraged from using hand sanitizer, urinating, changing clothes, moving her bowels, or rinsing out her mouth. She will need to be photographed by law enforcement personnel as well, and the photographic record needs to be as accurate as possible. If the patient cannot be dissuaded from taking these actions, then respect her feelings.

Some patients may refuse transport altogether. For adults who are mentally competent, this is the patient’s right. In such cases, you should follow your system’s refusal of treatment policy or procedure for sexual assault victims without judging or being condescending to the patient. In no instance should you simply accept the patient’s refusal and leave. Offer to call the local rape crisis center for the patient. Many communities have rape crisis centers, with victim advocates on-call. Getting a professional advocate to the scene may help the patient deal with the trauma, and the advocate can better explain the necessities of evidence preservation in more compassionate detail. Many victim advocates are rape-trauma survivors themselves. Always follow your local protocol concerning this type of call.

The patient care report is a legal document and, should the case result in an arrest and subsequent trial, may be subpoenaed. Keep the report concise, and record only what the patient stated in her own words. Use quotation marks to indicate that you are reporting the patient’s version of events. Do not insert your own opinion as to whether the patient was raped or offer any conclusions that would validate or invalidate the patient’s account of the event. Focus on the facts. Record your observations during the physical examination—the patient’s emotional state, the condition of her clothing, and any obvious injuries. Bear in mind that rape is a *legal* diagnosis, not a medical diagnosis. The medical team can establish only whether sexual intercourse occurred; a court must decide whether intercourse was inflicted forcibly on the victim, against her will.

Drugs Used to Facilitate Rape

It is not uncommon for drugs to be involved when a rape or other sexual assault has taken place. Alcohol is a common element to rape scenes. Other drugs used in the commission of the crime of rape include “club drugs” such as Rohypnol (roofies), GHB (liquid E or liquid ecstasy), ketamine (Special K), Klonopin, and Xanax. These drugs can be put into a person’s drink and may go undetected because they often do not have a color, smell, or taste. The effects may be immediate. The patient may become weak and confused and may even have a loss of consciousness. If the drugs are still in the patient’s system during your assessment, then you may see hypotension, bradycardia, difficulty breathing, seizures, coma, and even death.

Sexual Practices and Vaginal Foreign Bodies

There is a variety of ways in which men and women engage in sexual acts. Your exposure to these practices will most likely occur when these private sexual practices go bad, resulting in an embarrassing call to 9-1-1.

The most common sexual-related emergency you may encounter is simply a foreign object (a beverage or beer bottle, or a sex toy) that has become stuck in the vagina or rectum. For example, a bottle may develop a vacuum inside of the body and stick to an interior structure. Attempts at removal by the patient may result in intense pain or even vaginal

bleeding as internal structures tear. Bleeding and pain may cause the patient to panic. With this type of call, keep the patient calm, protect the patient's dignity as much as possible, and transport. Do not attempt to remove any foreign objects from the vagina or anus. If at all possible, do not let the patient walk. Overpenetration of any item may lead to internal injury, and should be managed as such.

Some cases of bottle insertion may be associated with rape, so bear in mind that the patient may be an assault victim. Some gangs have been known to insert beer bottles in a woman's vagina after rape, and then take turns punching the woman in the lower abdomen until the bottle breaks. If this is the case, use extreme care and do not move the patient more than necessary to prevent even more internal damage.

Among the more unusual sexual practices you may encounter is the technique known as "fisting," which involves placing the closed fist and wrist into a body orifice (vagina or rectum) for

sexual stimulation. Whether the patient is male or female, organ rupture (rectum, vagina) is possible. Life-threatening peritonitis may result. Another sexual practice is the insertion of live animals into the vagina or rectum, including fish, eels, snakes, worms, and hamsters. The patient becomes alarmed when the animal goes in but does not come out.

Assessment in this situation is sensitive. Maintain your patient's privacy. Depending on the circumstances, you may need to inspect the genital area for bleeding, wounds, or objects that may need to be stabilized. Avoid focusing on only one part of your patient; you still need to conduct a thorough patient assessment including vital signs and history.

Treat such a case as you would with any other foreign object, remain nonjudgmental, and transport. Do not attempt to retrieve the object, even if it is an animal, from inside the vagina or rectum. Transport the patient in a knees-flexed, legs-together position.

YOU are the Provider SUMMARY

1. Should this patient be encouraged to bathe?

This patient should be discouraged from bathing, voiding, or cleaning any wounds until hospital personnel have completed a sexual assault assessment. If she insists on urinating, then have her do so in a sterile urine container (if available). Also, have her deposit the toilet paper in a paper bag. Seal and mark the bag for the police. This can be critical evidence.

2. What are the possible medical impacts of a sexual assault on this patient?

Because of the unknown health status of the assailant, the patient could be exposed to any number of STIs, including chlamydia, gonorrhea, HIV, cytomegalovirus, genital herpes, and syphilis. The risk of transmission of several diseases can be mitigated by appropriate postexposure prophylaxis, which can be provided at the hospital.

3. If available, should a female provider accompany the patient in the rear of the ambulance?

Having a same-gender provider accompany the patient in the rear of the ambulance may relieve the patient's anxiety. Because of the vulnerable nature of

these types of patients, a provider of the same gender may be better able to provide emotional support for the patient.

4. What kind of care does this patient require en route to the hospital?

This patient requires supportive care, as well as strong emotional support.

5. Does this type of call require any special documentation?

Documentation of a sexual assault call will need to be completed in extreme detail, to include the patient's history, assessment, treatment, and response to treatment. It is important to not speculate or interject opinion, but only to record the facts.

6. If you are able to preserve the patient's clothing in a bag for evidence, then in what type of bag should you place the clothing?

The patient's clothing should be placed in paper (not plastic) bags that are either carried on the ambulance or provided by law enforcement officers on scene. Plastic bags will allow for condensation to form, altering the evidence.

Narrative

EMS called to above location for a female who was sexually assaulted. On arrival, patient found ambulatory on scene, speaking with Officer Feakes with GCSO (Badge #302). Patient states she was making a late-night snack in her kitchen when an unknown Caucasian male broke into her house and sexually assaulted her with vaginal penetration. Patient is visibly upset, stating that the "Bastard didn't even use a condom" and that she feels dirty and would like to bathe. GCSO 302 and I relay the importance of evidence preservation by not bathing, and the patient states she will wait until she gets to the ED. Patient denies any vaginal bleeding or other associated trauma from the assault. Assisted the patient to the stretcher and secured in a position of comfort. En route to Northern Rockies Medical Center the patient states, "I don't know what I did to deserve this" and that she "just wants to be left alone." Patient reassured that this was not her fault and she did nothing to deserve it. Report called to ED with condition and ETA. On arrival, care and report given to RN without incident.

End of report

Prep Kit**Ready for Review**

- Occasionally, you will be called for a patient experiencing a gynecologic emergency unrelated to pregnancy. The problem may include excessive bleeding, soft-tissue injuries, or infection.
- The reproductive system is very vascular, and there is a great potential for massive hemorrhage. Familiarity with a woman's anatomy

and normal physiology will prepare you to assess and treat most common gynecologic conditions.

- Menstruation is the cyclic shedding of the uterine lining that usually occurs when no fertilized egg implants. Conditions associated with abnormalities of the menstrual cycle include

premenstrual syndrome, mittelschmerz, and amenorrhea; prehospital treatment for these conditions is predominantly supportive.

- Disorders in the female reproductive system can lead to gynecologic emergencies. These disorders include acute or chronic infection, hemorrhage, rupture of a cyst, and rupture of an ectopic pregnancy.
- Pelvic inflammatory disease (PID) is caused by an acute or chronic infection in the organs of the female pelvic cavity. The chief symptoms of PID are pelvic pain and fever, which typically occur within 1 week of the menstrual period.
- STIs are the primary infection that can lead to PID.
- Bacterial vaginosis is an infection in which normal bacteria in the vagina are replaced by an overgrowth of other bacteria. Symptoms may include itching, burning, or pain and may be accompanied by a “fishy,” foul-smelling discharge.
- Chancroid is caused by infection. Signs and symptoms include painful sores (usually of the genitals), and swollen, painful lymph glands or inguinal buboes in the groin area; some women may be asymptomatic.
- Chlamydia is a common STI with symptoms that are usually mild or absent, although some women may have lower abdominal pain, low back pain, nausea, fever, pain during intercourse, or bleeding between menstrual periods.
- Cytomegalovirus is a member of the herpesvirus family. In its active stages, this infection may produce prolonged high fever, chills, headache, malaise, extreme fatigue, and an enlarged spleen.
- Genital herpes is an infection of the genitals, buttocks, or anal area caused by herpes simplex virus, type 1 or type 2. An outbreak of herpes first causes small red bumps that develop into small blisters, then become itchy, painful sores. Other symptoms include fever, muscle aches and pains, headache, dysuria, vaginal discharge, and swollen glands in the groin area.
- Gonorrhea is an STI whose symptoms include dysuria (painful urination), with associated burning or itching, a yellow or bloody vaginal discharge, usually with a foul odor, and occult blood associated with vaginal intercourse. More severe infections may present with cramping and abdominal pain, nausea and vomiting, and bleeding between periods; these symptoms indicate that the infection has progressed to PID.
- Genital warts are caused by the human papillomavirus. Some infected people have no symptoms. In others, multiple growths develop in the genital areas.
- Syphilis causes signs and symptoms that mimic other diseases. A person with syphilis may remain asymptomatic for years, or have symptoms such as sores, rash, mucous membrane lesions, fever, swollen lymph glands, sore throat, patchy hair loss, headaches, weight loss, muscle aches, and fatigue.
- Trichomoniasis is caused by a single-celled protozoan parasite. The infected person may be asymptomatic or may experience signs and symptoms including a frothy, yellow-green vaginal discharge with a strong odor, as well as irritation and itching of the female genital area, discomfort during intercourse, dysuria, and lower abdominal pain.
- Symptoms of a vaginal yeast infection include itching, burning, soreness in the vagina and around the vulva, and vulvar swelling. Some women may report a thick, white vaginal discharge (“cottage cheese” appearance), pain during sexual intercourse, and burning on urination.
- A ruptured ovarian cyst can cause gynecologic/abdominal pain. An ovarian cyst is a fluid-filled sac attached to the inside or outside of the ovary. Such cysts may need to be removed surgically to relieve pressure or to treat infection.
- Ectopic pregnancy is a pregnancy that develops outside the uterus, most often in a fallopian tube. Symptoms include vaginal bleeding. Consider the possibility of an ectopic pregnancy in any female of reproductive age who has abdominal pain.
- Vaginal bleeding may be caused by normal menstruation, spontaneous abortion

(miscarriage), placenta previa, abruptio placentae, or trauma, among other causes.

- Endometritis is an inflammation or irritation of the endometrium; it is treated with antibiotics. Left untreated, it may lead to septic shock or cause spontaneous abortion in a pregnant patient.
- Endometriosis is a painful condition in which endometrial tissue grows outside the uterus; it often causes infertility. Prehospital care of the patient with endometriosis includes pain relief, placing the patient in a position of comfort, and use of dressings in case of vaginal bleeding.
- Postpartum eclampsia should be suspected when a woman has seizures and hypertension and has delivered a baby a few weeks earlier. Paramedic backup is required in such a case.
- Most patients experiencing a gynecologic emergency will be treated in the same manner regardless of the cause. Bleeding should be controlled, and the patient's ABCDEs should be assessed and monitored closely. Watch for developing signs of shock, and treat appropriately. Provide transport to the closest appropriate facility.
- Patient history has a major role when you are caring for a patient with a gynecologic emergency. Along with a detailed history of the present illness, ask the patient about any previous gynecologic problems and her obstetric history. Consider the possibility of ectopic pregnancy in any patient of childbearing age with abdominal pain.
- Always question the patient in privacy to maintain confidentiality.
- Perform a detailed physical examination, with close attention to preserving the patient's privacy. Expose only the areas that you need to examine, and cover the patient with a sheet. Monitor the patient closely for changes that may indicate shock is developing.
- Excessive bleeding is a serious emergency. Cover the vagina with a sterile pad; change the pad as often as necessary, and take all used pads to the hospital for examination. Pharmacologic interventions are generally not indicated. Contact medical control for further instructions.
- Use local pressure and a diaper-type bandage to hold dressings in place when treating nonobstetric injuries to the external genitalia. Never place dressings in the vagina. Treat patients with these injuries as you would any other victim of blood loss.
- When the patient is potentially in shock, place her in the shock position dictated by local protocol and keep her warm.
- Patients with PID generally walk doubled over guard the abdomen, and appear ill. Care includes placing the patient in a position of comfort and transport to an appropriate facility.
- Patients with a ruptured ovarian cyst usually have unilateral pain that may radiate from the abdomen to the back. Rupture of the cyst may result in some vaginal bleeding.
- Patients with a potential ectopic pregnancy usually present with signs of hypovolemic shock. Monitor the patient and establish a second IV line with a large-bore catheter. Place the patient in the shock position dictated by local protocol. Transport the patient rapidly to the closest appropriate facility.
- Treat patients with heavy vaginal bleeding on the basis of presenting signs and symptoms.
- Patients who have experienced abdominal trauma generally present with a variety of signs and symptoms that can include severe bleeding, pain, and hypovolemic shock. Management should be based on patient presentation.
- In the case of sexual assault or rape, treat for shock if necessary, and record all the facts in detail. Follow any crime scene policy established by your system to protect the scene and any potential evidence. Discourage the patient from washing, douching, or voiding until after the patient has been examined by a physician.
- A common sexual-related emergency an AEMT may encounter is a foreign object that has become stuck in the vagina or rectum. Keep the patient calm, protect the patient's dignity as much as possible, and transport; do not attempt to remove the foreign object.

Vital Vocabulary

abortion Delivery of the fetus and placenta before 20 weeks' gestation; a spontaneous abortion is called a miscarriage.

abruptio placentae Premature separation of the placenta from the wall of the uterus.

amenorrhea Absence of menstruation.

anus The outlet of the rectum.

bacterial vaginosis An overgrowth of bacteria in the vagina, characterized by itching, burning, or pain, and possibly a "fishy" smelling discharge.

cervix The lower one-third, or neck, of the uterus.

chancroid A highly contagious sexually transmitted infection caused by the bacteria *Haemophilus ducreyi*, which causes painful sores (ulcers), usually of the genitals.

chlamydia A sexually transmitted infection caused by the bacterium *Chlamydia trachomatis*.

clitoris Located in the anterior margin of the vestibule and partially hidden by the labia minora, it contains erectile tissue that becomes engorged with blood as a result of sexual excitement.

cytomegalovirus (CMV) A herpesvirus that can produce the symptoms of prolonged high fever, chills, headache, malaise, extreme fatigue, and an enlarged spleen.

dysmenorrhea Painful menstruation.

ectopic pregnancy A pregnancy that develops outside the uterus, typically in a fallopian tube.

endometriosis A condition in which endometrial tissue grows outside the uterus.

endometritis An inflammation of the endometrium that often is associated with a bacterial infection.

endometrium The innermost layer of the uterine wall.

fallopian tubes The two hollow tubes or ducts that extend from the uterus to the region of the ovary and serve as a passage for the egg and sperm.

fundus The uppermost part of the uterus, farthest from the cervical opening.

genital herpes An infection of the genitals, buttocks, or anal area caused by herpes simplex virus, which may cause sores of the genitals, mouth, or lips.

gonorrhea A sexually transmitted infection caused by *Neisseria gonorrhoeae*.

human papillomavirus (HPV) The most common sexually transmitted infection, caused by a virus, which may cause no symptoms or cause multiple growths in the genital areas.

hymen A fold of mucous membrane that partially covers the entrance to the vagina.

labia majora Two prominent, rounded folds of skin lateral to the labia minora of the female external genitalia.

labia minora A pair of skin folds in the female external genitalia that border the vestibule.

menarche The initial onset of menstruation occurring during puberty; the first menstrual cycle.

menopause The cessation of the menstrual cycle and ovarian function.

menstruation The period in the menstrual cycle of sloughing and discharge of the functional layer of the endometrium; occurs approximately every 28 days.

mons pubis The pad of fatty tissue and coarse skin that lies over the pubic symphysis.

myometrium A thick smooth muscle that forms the middle layer of the uterine wall.

oocytes Female sex cells; the precursors to a mature egg.

ovaries Glands that lie on either side of the pelvic cavity in a woman and produce sex hormones and ova (eggs).

pelvic inflammatory disease (PID) An infection of the female upper organs of reproduction, specifically the uterus, ovaries, and fallopian tubes.

perineum The area of skin between the scrotum and the anus in males, and the vagina and the anus in females.

placenta previa A condition in which the placenta develops over and partially or completely covers the cervix.

premenstrual syndrome (PMS) A cluster of all or some of the troubling symptoms that occur during a woman's menstrual phase that can include fluid retention, breast pain and tenderness, headache, severe cramping, and emotional changes, including agitation, irritability, depression, and anger.

prepuce A structure in the female external genitalia that is formed where the labia minora unite over the clitoris.

rape The penetration of the vagina or anus with any body part or object, or oral penetration by a sex organ, against the victim's will.

sexual assault An attack against a person that is sexual in nature, the most of common of which is rape.

syphilis A sexually transmitted infection caused by the bacterium *Treponema pallidum*, which manifests in three stages—primary, secondary, and tertiary—and is transmitted through direct contact with open sores.

trichomoniasis A parasitic infection.

urethra The canal that conveys the discharge of urine, extending from the urinary bladder to the outside of the body.

uterus The muscular organ where the fetus grows, also called the womb; responsible for contractions during labor.

vagina The muscular tube that forms the lower part of the female reproductive tract; connects the uterus with the vulva (the external female genitalia); also called the birth canal.

vaginal orifice Opening of the vagina.

vaginal yeast infections Infections caused by the fungus *Candida albicans*, in which fungi overpopulate the vagina.

vestibule Small space at the beginning of an opening.

vulva The visible female external genitalia; also called the pudendum.

Chapter 26

Trauma Overview

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Trauma Overview

Pathophysiology, assessment, and management of the trauma patient

- Trauma scoring (p 1269)

- Rapid transport and destination issues (pp 1264–1268)
- Transport mode (pp 1265–1266)

Multisystem Trauma

Recognition and management of

- Multisystem trauma (pp 1242, 1261)
- Pathophysiology, assessment, and management of
- Multisystem trauma (pp 1261–1264)
 - Blast injuries (pp 1258–1260)

KNOWLEDGE OBJECTIVES

1. Define the term mechanism of injury (MOI), and explain its relationship to potential energy, kinetic energy, and work. (pp 1239–1242)
2. Define the term index of suspicion, and explain its relationship to the advanced emergency medical technician's (AEMT's) assessment of trauma. (pp 1239, 1243)
3. Define the terms blunt trauma and penetrating trauma, and provide examples of the MOI that would cause each one to occur. (pp 1242–1243)
4. Describe the five types of motor vehicle collisions, the injury patterns associated with each one, and how each relates to the index of suspicion of life-threatening injuries. (pp 1243–1252)
5. Discuss the three specific factors to consider during assessment of a patient who has been injured in a fall, plus additional considerations for pediatric and geriatric patients. (pp 1255–1256)
6. Discuss the effects of high-, medium-, and low-velocity penetrating trauma on the body and how an understanding of each type helps the AEMT form an index of suspicion about unseen life-threatening injuries. (pp 1256–1258)
7. Discuss primary, secondary, tertiary, and miscellaneous blast injuries, and describe the anticipated damage each one will cause to the body. (pp 1258–1260)
8. Describe multisystem trauma and the special considerations that are required for patients who fit this category, and provide a general overview of multisystem trauma patient management. (p 1261)
9. Outline the major components of trauma patient assessment, including considerations related to whether the MOI was significant or nonsignificant. (p 1262)
10. Discuss the special assessment considerations related to a trauma patient who has injuries in each of the following areas: head, neck and throat, chest, and abdomen. (pp 1262–1264)
11. Describe trauma patient management in relation to scene time, type of transport, and destination selection and list the Association of Air Medical

- Services criteria for the appropriate use of emergency air medical services. (pp 1264–1268)
12. Discuss the facilities and transport resources available through emergency medical services (EMS) trauma systems. (pp 1261, 1265–1266)
13. Describe the American College of Surgeons' Committee on Trauma classification of trauma centers and how it relates to making an appropriate destination selection for a trauma patient. (pp 1266–1268)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

According to the US Centers for Disease Control and Prevention (CDC), unintentional injury is the primary cause of death and disability in people between ages 1 and 44 years.^{1,2} Proper prehospital evaluation and care can do much to minimize suffering, long-term disability, and death from trauma. Understanding the basic physical concepts that determine how injuries occur and affect the human body will allow you to size up a crash scene and use that information as a vital part of patient assessment.

This chapter begins with a basic discussion of energy and trauma. Next, different types of vehicle crashes and their effects on the body are explained. Evaluation of the **mechanism of injury (MOI)** for the trauma patient will provide the advanced emergency medical technician (AEMT) with an **index of suspicion** for different types of serious and/or life-threatening underlying injuries. Certain injury patterns occur with certain types of injury events. The index of suspicion is your awareness and concern for potentially serious underlying and unseen injuries. The amount of energy exchanged also has a major effect on the severity of injuries, along with the anatomic structures potentially involved. All of these factors will influence your approach to assessing and treating trauma patients in the field.

Energy and Trauma

Traumatic injury occurs when the body's tissues are exposed to energy levels beyond their tolerance (**FIGURE 26-1**). The MOI is the way in which traumatic injuries occur; it describes the forces (or energy transmission) acting on the body that cause injury. Three concepts of energy are typically associated with injury (not including thermal energy, which causes burns): **potential energy**, **kinetic energy**, and the energy of **work**. When considering

FIGURE 26-1 A ruptured spleen. Traumatic injury occurs when the body's tissues are exposed to energy levels beyond their tolerance.

the effects of energy on the human body, it is important to remember that energy can be neither created nor destroyed, but can only be converted or transformed. It is not the objective of this section to help you to reconstruct the scene of a motor vehicle crash. Rather, you should have a sense of the effects of the event on the human body and understand, in a broad sense, how that work is related to potential and kinetic energy.

Work is defined as force acting over a distance. For example, the force needed to bend metal

multiplied by the distance over which the metal is bent is the work that crushes the front end of a vehicle that is involved in a frontal impact. Similarly, forces that bend, pull, or compress tissues beyond their inherent limits result in the work that causes injury.

Different forms of energy produce different kinds of trauma. These external energy sources can be kinetic, potential, mechanical, chemical, electromagnetic, thermal, nuclear, or ionization.

Mechanical energy is energy from motion. Mechanical energy is subdivided into two types mentioned previously: kinetic energy (such as a moving vehicle) and potential energy (energy stored in an object, such as a brick sitting on a building ledge).

Kinetic energy reflects the relationship between the mass (weight) of the object and the velocity (speed) at which it is traveling and would be found in the force of two moving vehicles colliding. Kinetic energy is expressed as:

$$\text{Kinetic energy} = (\frac{1}{2} \times \text{Mass}) \times \text{Velocity}^2, \\ \text{or KE} = \frac{1}{2} m \times v^2$$

Remember that energy cannot be created or destroyed, only converted. In the case of a motor vehicle crash, the kinetic energy of the speeding vehicle is converted into the work of stopping the vehicle, usually by crushing the vehicle's exterior (**FIGURE 26-2**). Similarly, the passengers of the vehicle have kinetic energy because they were traveling at the same speed as the vehicle. Their kinetic energy is converted to the work of bringing them to a stop. It is this work on the passengers that results in injury. Notice that, according to the equation for

FIGURE 26-2 In a motor vehicle collision, the kinetic energy of the speeding vehicle is converted into the work of stopping the vehicle, usually by crushing the vehicle's exterior.

© Terry Dickson, Florida Times-Union/AP Photo.

kinetic energy, the energy that is available to cause injury *doubles* when an object's weight doubles but *quadruples* when its speed doubles. When a vehicle's speed increases from 50 to 70 mph, the energy that is available to cause injury doubles. This point is even clearer when considering gunshot wounds. The speed of the bullet (high velocity compared with low velocity) has a greater effect on producing injury than the mass (size) of the bullet. This is why it is so important to report to the hospital the type of firearm that was used in a shooting. The amount of kinetic energy that is converted to do work on the body determines the severity of the injury. High-energy injuries often produce such severe damage that only immediate transport to an appropriate facility may save the patient.

YOU are the Provider

Part 1

Your ambulance is dispatched to a motor vehicle collision just outside of town. As you advise your dispatch that you are responding, you are told this incident is the result of a high-speed police pursuit and the fleeing car rear-ended a small pickup truck at a stop sign. Officers advise the impact was approximately 85 to 90 mph, and they believe that the driver of the fleeing car is dead.

1. On the basis of the information provided, what are some possible injuries you may encounter?
2. With the understanding that patients at this scene are most likely critical, how long should you remain on scene?

Words of Wisdom

Newton's First Law

Newton's first law states that objects at rest tend to stay at rest and objects in motion tend to stay in motion unless acted on by some outside force. An example of the first part of the law is an empty soda can that will not move spontaneously unless some force, such as a gust of wind, acts on it. An example of the second part might be as follows: In a vehicle going 50 mph that strikes a concrete barrier and comes to a sudden stop, the passengers continue to travel forward at 50 mph. They stay in motion until they are acted on by an external force—most likely the seat belt, windshield, steering wheel, or dashboard. The same thing happens to the driver's internal organs, which are acted on by the sternum, rib cage, or other body structure. This scenario illustrates the three collisions that are associated with blunt trauma.

Newton's Second Law

Newton's second law states that force (F) equals mass (m) times acceleration (a)—that is, $F = m \times a$ —in which acceleration is the change in velocity (speed) that occurs over time. This change can be positive (acceleration) or negative (deceleration). Therefore, $\text{Mass} \times \text{Acceleration} = \text{Force} = \text{Mass} \times \text{Deceleration}$.

In the example of a vehicle traveling at 30 mph, it takes approximately 3 seconds for the car to decrease its speed from 30 to 0 mph when the driver applies the brakes smoothly. The driver slows, or decelerates, at the same rate as the vehicle. But if the vehicle is stopped not by braking but by hitting a large tree and the driver is not restrained, the driver's body will continue to stay in motion at 30 mph until it is stopped by an external force: in this case, by hitting the steering wheel. Although the change in the body's velocity is the same as when the vehicle was braking smoothly in 3 seconds (30 to 0 mph), that change now takes place in approximately 0.01 second. Because the period of **deceleration** is 300 times less, the average force of impact is 300 times greater. This means that the force is approximately 150 times the force of gravity. Imagine a force 150 times your body weight slamming into your chest.

Now consider the same vehicle striking the same tree, but this time, the driver is restrained with a shoulder and lap belt. The driver is essentially tied to the vehicle and stops during the same period the vehicle stops. It takes some time, although brief, to crush the front of the car and bring it to a halt. The vehicle comes to a stop in approximately 0.05 second. The change in the driver's velocity is the same (30 to

0 mph), but the longer period of deceleration results in a *g* force of only 30 times that of gravity (one *g* force is the normal acceleration due to gravity). This is still a substantial force, but it is much less than the force experienced by the unrestrained driver. More to the point, it is survivable.

In a final example, the vehicle and driver, as before, are traveling at 30 mph, and the driver is properly restrained with a three-point belt. In this case, however, the vehicle is also equipped with an airbag. When the vehicle hits the tree and suddenly stops, the driver's upper body initially continues forward at 30 mph. The body is partially slowed by the lap and shoulder belts but is finally brought to rest by the airbag. The upper body compresses the airbag, which stops the body's forward motion in approximately 0.1 second. Thus, the airbag stretches the duration of impact by 0.05 second, buying the body even more time, and the force on the upper body decreases to approximately 15 times that of gravity.

The airbag has another advantage that, coupled with increasing the duration of impact, results in less severe injuries. The force of its impact is applied over a much larger area than the area affected by the steering wheel or the shoulder belt, shrinking the force per unit area. This point can be illustrated by an analogy. A person standing on one toe on a sheet of ice applies a concentrated load in a very small area, thus breaking the ice and falling through. If the person lies flat on the ice, the person greatly expands the contact area and reduces the stress on the ice, making it less likely to break. The dual action of the airbag (distributing the force of impact over a greater area and increasing the duration of impact) results in less severe injuries.

Newton's Third Law

Newton's third law states that for every action, there is an equal and opposite reaction. Therefore, if you push on a door, the door pushes back (reacts) with an equal force but in the opposite direction. In the case of a dented A-pillar, the force of the driver's head was sufficient to dent the strong metal. But with patient assessment, the more important point is the reaction force of the pillar on the head. Regarding Newton's third law, the head was essentially hit by an A-pillar traveling at 30 mph. Similarly, it takes a substantial force to collapse a steering wheel. When you notice a collapsed steering wheel during scene size-up, suspect serious chest injuries, even if the driver initially has no visible signs of chest injury.

Potential energy is the product of mass (weight), force of gravity, and height and is mostly associated with the energy of falling objects. It would be present in an object sitting at a height. In that case, gravity would be the *potential* source of energy that converts to kinetic energy if the object falls. A worker on a scaffold has some potential energy by being some height above the ground. If the worker falls, potential energy is converted into kinetic energy. As the worker hits the ground, the kinetic energy is converted into work, that is, the work of bringing the body to a stop and thereby fracturing bones and damaging tissues.

Chemical energy is the energy released as a result of a chemical reaction and can be found in an explosive, an acid, or even from a reaction to an ingested or medically delivered agent or drug. **Thermal energy** is energy transferred from sources that are hotter than the body, such as a flame, hot water, and steam. **Electrical energy** comes in the form of high-voltage electrocution or a lightning strike. **Barometric energy** can result from sudden and radical changes in pressure, as can occur during scuba diving or flying in an unpressurized cabin.

Kinetics studies the relationships among speed; mass; direction of the force; and, for AEMTs, the physical injury caused by speed, mass, and force. Knowledge of kinetics can help you predict injury patterns found in your patient.

Mechanism of Injury Profiles

Different types of MOIs will produce many types of injuries. Some will involve an isolated body system; many will result in injury to more than one body system. Injuries sustained by trauma patients may be the result of **multisystem trauma** (injury to more than one body system), falls from heights, motor vehicle and motorcycle crashes, vehicle versus pedestrian (or bicycle or motorcycle), gunshot wounds, and stab-bings. Whether one body system or more than one system is involved, maintain a high index of suspicion for serious unseen injuries. **TABLE 26-1** lists significant MOIs that you will read about in this chapter.

Blunt and Penetrating Trauma

Traumatic injuries can be described in two separate categories: **blunt trauma** and **penetrating trauma**.

TABLE 26-1 Significant Mechanisms of Injury

Age	Mechanisms
Adults	• Multiple body systems injured • Ejection from a vehicle • Death of another person in the same vehicle • Fall from a height >20 feet (6 m) • Vehicle rollover (unrestrained) • High-speed (>40 mph) vehicle crash • Vehicle-pedestrian collision • Motorcycle crash of >20 mph • Unresponsiveness or altered mental status following trauma • Penetrating trauma to the head, chest, or abdomen
Children	All mechanisms in the adult list, with the following additions or modifications: • Fall >10 feet (3 m) or two to three times the child's height • Fall of <10 feet (3 m) with loss of consciousness • Medium- to high-speed vehicle crash (≥25 mph) • Bicycle crash

© Jones & Bartlett Learning.

Blunt trauma is the result of force (or energy transmission) to the body that causes injury primarily without anything penetrating the soft tissues or internal organs and cavities. Penetrating trauma results in injury by objects that pierce and penetrate the surface of the body and injure the underlying soft tissues, internal organs, and body cavities. Either type of trauma may occur from a variety of MOIs. It is important for you to consider unseen as well as visible, obvious injuries with either type of trauma. Damage to the underlying deeper tissues is often more substantial.

Words of Wisdom

The top five causes of death from unintentional injury in the United States are poisoning (specifically opioid overdose), motor vehicle crashes, falls, choking and suffocation, and drowning.³

Blunt Trauma

Blunt force trauma results from an object making contact with the body. Any object (eg, a baseball bat) can cause blunt trauma if it is moving fast enough. Motor vehicle crashes and falls are two of the most common MOIs for blunt trauma. Be alert to signs of skin discoloration or reports of pain because these may be the only signs of blunt trauma. Maintain a high index of suspicion during patient assessment for hidden (internal) injuries in patients with blunt trauma.

Motor Vehicle Crashes

In 2018, according to the National Highway Traffic Safety Administration (NHTSA), 33,654 people were killed in police-reported motor vehicle traffic crashes, and 2.71 million people were injured.⁴ That calculates to almost 100 people dying and more than 7,425 people being injured in motor vehicle crashes every day in the United States.

Motor vehicle crashes are classified traditionally as frontal (head-on), rear-end, lateral (T-bone), rollovers, and rotational (spins). The principal difference among these crash types is the direction of the force of impact; also, with spins and rollovers, there is the possibility of multiple impacts. Motor vehicle crashes typically consist of a series of three collisions. Understanding the events that occur during each collision will help you be alert for certain types of injury patterns. The three collisions in a typical impact are as follows:

1. The collision of the vehicle against another vehicle, a tree, or some other object. Damage to the vehicle is perhaps the most dramatic part of the collision, but it does not directly affect patient care, except possibly to make extrication difficult (**FIGURE 26-3**). However, it does provide information about the severity of the collision and, therefore, has an indirect effect on patient care. The greater the damage to the vehicle, the greater the energy that was involved and, therefore, the greater the potential to cause injury to the patient. By assessing the vehicle that has crashed, you can often determine the MOI, which may allow you to predict what injuries may have happened to the passengers at the time of impact according to forces that acted on their bodies. When you arrive at the crash scene and perform your scene
2. The collision of the passenger against the interior of the vehicle. Just as the kinetic energy produced by the vehicle's mass and velocity is converted into the work of bringing the vehicle to a stop, the kinetic energy produced by the passenger's mass and velocity is converted into the work of stopping the body (**FIGURE 26-4**). Just like the obvious damage to the exterior of the vehicle, the injuries that result are often dramatic and usually immediately apparent during your scene size-up or primary survey. Common injuries include lower extremity fractures (knees into the dashboard), rib fractures (rib cage into the steering wheel), and head trauma (head into the windshield). Such injuries occur more frequently if the passenger is not restrained. But even when the passenger is restrained with a properly adjusted seat

FIGURE 26-3 The first collision in a typical impact is that of the vehicle against another object (in this case, a utility pole). The appearance of the vehicle can provide you with critical information about the severity of the crash. The greater the damage to the vehicle, the greater the energy that was involved.

© Rockettegg/iStock /Getty Images Plus/Getty Images.

belt, injuries can occur, especially in lateral and rollover impacts.

3. The collision of the passenger's internal organs against the solid structures of the body. The injuries that occur during the third collision may not be as obvious as external injuries, but they are often the most life threatening.

FIGURE 26-4 The second collision in a frontal impact is that of the passenger against the interior of the vehicle. Examining the interior of the vehicle may give you clues to hidden injuries.

Courtesy of Rhonda Hunt.

For example, as the passenger's head hits the windshield, the brain continues to move forward until it comes to rest by striking the inside of the skull. This results in compression injury (or bruising) to the anterior portion of the brain and stretching (or tearing) of the posterior portion of the brain (**FIGURE 26-5**). Remember that for every action there is an equal and opposite reaction. As the brain strikes the front of the skull, the body begins its path of

FIGURE 26-5 The discolored spots show injuries (contusions) in this brain.

YOU are the Provider

Part 2

As you arrive on scene, you find an unidentifiable car with substantial front-end damage and a small pickup truck with severe rear-end damage. You immediately assign your partner to the patient in the pickup truck while you assess the patient in the car. You find the patient unrestrained, pulseless, and apneic, with severe facial trauma and exposed brain matter from the impact with the windshield. You tag the patient "Black" according to your triage protocols, and inform the officers that he is dead.

As you join your partner, she informs you that the patient is severely entrapped and has a Glasgow Coma Scale (GCS) score of 4 (E-1, V-2, M-1). You request that the fire department upgrade their response to a rescue assignment and also request your local flight service for aeromedical evacuation.

Recording Time: 1 Minute

Appearance	Poor
Level of consciousness	Unresponsive, moans to pain
Airway	Patent
Breathing	8 breaths/min, shallow
Circulation	Cool, pale, and clammy

3. To which type of hospital should this patient be transported?

FIGURE 26-6 The third collision in a typical impact is that of the passenger's internal organs against the solid structures of the body. A coup-contrecoup injury occurs when the brain continues its forward motion and strikes the inside of the skull, resulting in a compression injury to the anterior portion of the brain and stretching of the posterior portion.

© Jones & Bartlett Learning.

moving backward. The head falls back against the headrest and/or seat, and the brain slams into the rear of the skull. Damage is produced to both the front and rear of the brain. This type of injury is known as a **coup-contrecoup** injury (**FIGURE 26-6**). The same type of injury may occur on opposite sides of the brain in a lateral collision. Similarly, in the thoracic cage, the heart may slam into the sternum, occasionally rupturing the aorta and causing fatal bleeding.

Understanding the relationships among the three collisions will help you to make the connections between the amount of damage to the exterior of the vehicle and potential injury to the passenger. For example, in a high-speed crash that results in massive damage to the vehicle, you should suspect serious injuries to the passengers, even if the injuries are not readily apparent. Several potential physical problems may develop as a result of traumatic injuries. Your initial general impression of the patient and the evaluation of the MOI can help to direct life-saving care and provide critical information to the hospital staff. Therefore, if you see a contusion on the patient's forehead and the windshield is starred and pushed out, you should strongly suspect an injury to the brain. After you inform medical

control about the damage to the windshield, hospital staff can prepare for the patient by ordering a computed tomography scan of the brain. Without your input, the physician might have found the brain injury anyway, but it might not have been detected until the brain had swollen sufficiently to cause clinical signs of the injury. Whenever there is a substantial impact to the head, you should also consider the possibility of a spinal injury and take cervical spine precautions if indicated.

The amount of damage that is considered substantial varies, depending on the type of crash, but any substantial deformity of the vehicle should be enough cause for you to consider transporting the patient to a trauma center. Severe deformity of the vehicle or intrusion into the vehicle as listed here correlates to significant MOI:

- Severe deformities of the frontal part of a vehicle, with or without intrusion into the passenger compartment
- Moderate intrusions from a lateral (T-bone) type of collision
- Severe damage from the rear
- Crashes in which rotation is involved (roll-overs and spins)

Street Smarts

When a patient has died in a vehicle, others in the vehicle may be upset by the death and unaware of their own injuries. As with all patients, be sure to assess them thoroughly.

Damage to the vehicle that was involved and information obtained during scene size-up are not the only clues to crash severity. Clearly, if one or more of the passengers is dead, you should suspect that the other passengers have sustained serious injuries, even if the injuries are not obvious. Therefore, you should focus on treating life-threatening injuries and providing rapid transport to a trauma center, because these passengers have likely experienced the same amount of force that caused the death of the other passengers. Digital photos of the crash scene may provide valuable information to the staff and treating physicians of the trauma center; however, photos should never be shared over social media. Photos containing patient images or

other identifiable patient information may become part of the medical record or may need to be deleted after review by the receiving health care providers, depending on policies.

Patients should be assessed according to the area of the body that was most likely injured. Your evaluation should also be based, to some extent, on the patient's position in the vehicle, the use of seat

belts, airbag deployment, and how the patient's body shifted during the crash. Drivers are typically at higher risk for serious injury than passengers because of the potential for striking the steering wheel with the chest, abdomen, or head. Front seat passengers may also be injured by striking the dashboard or windshield.

TABLE 26-2 describes the structural clues, body clues, and resulting injuries for different types of crashes.

TABLE 26-2 Mechanism of Injury: Motor Vehicle Crash

Structural Clues	Body Clues	Potential Injuries
Head-on or Frontal Impact		
Deformed front end Cracked windshield	Bruised or lacerated head or face	Brain injury Scalp, facial cuts Cervical spine injury Tracheal injury
Deformed steering column	Bruised neck Bruised chest	Sternal or rib fracture Flail chest Myocardial contusion Pericardial tamponade Pneumothorax or hemothorax Exsanguination from aortic tear
Deformed dashboard	Bruised abdomen Bruised knee, dislocated patella	Ruptured spleen, liver, bowel, diaphragm Fractured patella Dislocated knee Femoral fracture Dislocated hip
Lateral or Side Impact		
Deformed side of vehicle	Bruised shoulder	Clavicular fracture Fractured humerus Multiple rib fractures
Door smashed in	Bruised shoulder or pelvis	Fractured hip Fractured iliac wing Fractured clavicle or ribs
B-pillar deformed	Bruised temple	Brain injury Cervical spine fracture
Broken door or window handles	Bruised or deformed arms	Contusions
Broken window glass	Dicing lacerations	Multiple lacerations
Rear-end Impact		
Posterior deformity of the vehicle	Secondary anterior injuries, especially if the patient was unrestrained	Whiplash injuries Deceleration injuries of a head-on impact
Headrest not adjusted	None detected	Bleeding, bruising, or tearing inside skull

Frontal Crashes

Understanding the MOI after a frontal crash first involves evaluation of the supplemental restraint system, including seat belts and airbags. You should determine whether the passenger was restrained by a full, properly applied three-point restraint. In addition, you should determine whether the airbag was deployed. Identifying the types of restraints used and whether airbags were deployed will help you identify injury patterns related to the supplemental restraint systems.

Words of Wisdom

When you are assessing trauma incidents, MOI is a crucial element of patient history. Be alert to the extent of damage to the interior and exterior of the vehicles involved in crashes. Use these observations to paint a picture of the scene for later caregivers in verbal and written communication.

When properly applied, seat belts are successful in restraining the passengers in a vehicle and preventing a second collision inside the motor vehicle. According to the NHTSA, seat-belt use saved an estimated 14,955 lives in 2017.⁵ In addition, they may decrease the severity of the third collision, that of the passenger's organs with the chest or abdominal wall. The protective abilities of seat belts are further enhanced by deployment of the airbags. Airbags provide the final capture point of the passengers and decrease the severity of deceleration injuries by allowing seat belts to be more compliant and by cushioning the occupant as the body slows, or decelerates.

Remember that airbags decrease injury to the chest, face, and head very effectively. However, you should still suspect that other serious injuries to the extremities (resulting from the second collision) and to internal organs (resulting from the third collision) have occurred.

Safety

Never place yourself or your patient in front of an undeployed airbag. Even if the battery cables are disconnected, a charge can be held in the line, allowing the airbag to deploy later, causing potentially severe injuries.

Most new motor vehicles are manufactured with airbag safety systems. These safety devices enhance the safety and survival of forward-facing occupants inside the vehicle during a crash. In an emergency braking event or crash, the airbag inflates very quickly. Because a rear-facing car seat is close to the dashboard, rapid inflation of the airbag could cause serious injury or death to an infant. All children who are shorter than 4 feet 9 inches (145 cm) should ride in the rear seat or, in the case of a pickup truck or other single-seated vehicle, the airbag should be turned off.

When you are providing care to an occupant inside a motor vehicle, it is important to remember that if the airbag did not inflate during the accident, it may deploy during extrication. If this occurs, you may be seriously injured or even killed. Exercise extreme caution when extricating a patient in a vehicle with an airbag that has not deployed. Consider not only front airbags, but also side airbags and those found over the windows in many vehicles.

Seat belts may also cause unseen abdominal injuries, particularly in pediatric patients. Seat belts are designed to be worn over the iliac crests of the pelvis to distribute the force over the bony surface. Hip injuries may result if seat belts are worn too low. Internal injuries can occur when the belt is worn too high, resulting in damage to abdominal organs (**FIGURE 26-7**). Lumbar spine fractures are also possible, particularly in elderly patients.

FIGURE 26-7 Injuries may result if the seat belt is worn too high or too low across the waist. Although less common, injuries can also result from seat belts worn in the correct position across the torso.

Courtesy of ED, Royal North Shore Hospital/NSW Institute of Trauma & Injury.

FIGURE 26-8 Airbags can cause injury in frontal crashes, specifically, abrasions, contusions, and traction-type injuries to the face, neck, and inner arms. This photo shows a seat-belt injury across the chest and airbag contusions on the left breast.

© G. Patrick/Science Source.

When passengers who are riding in vehicles equipped with airbags are not restrained by seat belts, they are often thrown forward in the act of emergency braking. As a result, they come in contact with the airbag and/or the doors at the time of deployment. This MOI is also responsible for some severe injuries to children who are riding unrestrained in the front seats of vehicles, unrestrained passengers, and those sitting too close to the airbag.

In addition, some passengers may pass out before impact, and you may find them lying against the deployed airbag. When you encounter these types of situations, look for abrasions and/or traction-type injuries on the face, lower part of the neck, and chest (**FIGURE 26-8**).

Contact points are often obvious from a simple, quick evaluation of the interior of the vehicle. If there is no intrusion into the passenger compartment, you might see that an unrestrained front-seat passenger in a frontal crash has come in contact with the dashboard or instrument panel at the knees, thus transferring energy from the knees through the femur to the pelvis and hip joint (**FIGURE 26-9A**). The chest and/or abdomen may also hit the steering wheel (**FIGURE 26-9B**). In

FIGURE 26-9 Mechanism of injury and condition of the vehicle interior suggest likely areas of injury. **A.** The knee can strike the dashboard, resulting in a hip fracture or dislocation. **B.** Serious chest and abdominal injuries can result from striking the steering wheel. **C.** Head and spinal injuries can result when the face and head strike the windshield.

© Jones & Bartlett Learning.

addition, the passenger's face often hits the steering wheel or may launch forward and up, hitting the windshield and/or the roof header in the area of the visors (**FIGURE 26-9C**). Signs of most of these injuries can be found by inspecting the interior of the vehicle during extrication of the patient.

Supplemental restraint systems can also cause harm whether they are used properly or improperly. For example, some older models have seat belts that buckle automatically at the shoulder but require the passengers to buckle the lap portion; these can cause the occupant to travel down and under the shoulder strap as the body continues forward, resulting in the lower body striking the dashboard. This movement of the body can cause the lower extremities and the pelvis to crash into the dashboard because that part of the body is unrestrained. People who do not wear seat belts are at much higher risk for multiple injuries because they may be catapulted through the car or ejected from the vehicle. If a patient is unrestrained and involved in a frontal collision, the person may be thrown up and over the steering wheel, resulting in the head hitting the windshield, roof, or rearview mirror. The chest may come in contact the steering column or dash, and the abdomen may also strike the steering column or dash. If the patient is driving, either femur or the pelvis may sustain substantial injury as contact is made with the bottom of the steering wheel. Finally, an unrestrained person may be ejected from the vehicle, dramatically increasing the risk of head injury, spinal cord injury, and death. **TABLE 26-3** lists injury patterns.

Ejection is possible if the windshield does not stop the body from penetrating through it. Ejection results in second-impact injuries when the body comes in contact with the ground or objects outside of the vehicle. These injuries can be as severe as initial-impact injuries, and they increase the likelihood of great vessel damage and death. The spine absorbs energy as it is compressed between the stationary head and the moving torso, which results in injury.

A dangerous lung injury may occur if your patient reflexively takes a deep breath just before impact, hyperinflating the lungs and closing the glottis. The impact of the steering wheel can injure the lungs by generating pressures in the lungs beyond the capabilities of the lung tissue, like a “paper bag being exploded.” This often results

in a pneumothorax (**FIGURE 26-10**). In addition, **TABLE 26-4** lists the “ring” of chest injuries that can occur from impact with the steering wheel or dashboard.

Rear-End Crashes

Rear-end impacts are known to cause whiplash-type injuries, particularly when the head and/or neck is not supported by an appropriately placed headrest (**FIGURE 26-11**). On impact, the vehicle seat pushes the body and torso forward. As the body is propelled forward, the head and neck are left behind because a headrest does not support them, and they appear to be whipped back relative to the torso. As the vehicle comes to rest, the unrestrained passenger moves forward, striking the dashboard. In this type of crash, the cervical spine and surrounding area may be injured. The cervical spine is less tolerant of damage when it is bent back. Headrests decrease extension of the head and neck during a crash and, therefore, help reduce injury. Other parts of the spine and the pelvis may also be at risk for injury. In addition, the patient may sustain an acceleration injury to the brain; that is, the third collision of the brain within

FIGURE 26-10 The paper-bag syndrome. **A.** The occupant takes a deep breath just before crashing, closing the glottis and filling the lungs with air. **B.** The occupant's chest hits the steering wheel, popping the alveoli in the lungs. **C.** A pneumothorax results.

the skull. Passengers in the backseat wearing only a lap belt might have a higher incidence of injuries to the thoracic and lumbar spine.

Lateral Crashes

Lateral, or side impacts (commonly called T-bone crashes) are a common cause of death associated with motor vehicle crashes. When a vehicle is struck from the side, it is typically struck above its center of gravity and begins to rock away from the side of the impact. This results in a lateral whiplash injury (**FIGURE 26-12**). The movement is to the side, and the passenger's shoulders and head whip toward the intruding vehicle. This action may thrust the shoulder, thorax, upper extremity, and, more important, the skull, against the doorpost or the window. The patient could experience rotation of the neck, lateral flexion, or a combination of both. Because the cervical spine is relatively unstable, it has little tolerance for lateral bending.

If there is substantial intrusion into the passenger compartment, suspect lateral chest and abdomen injuries on the side of the impact, as well as possible fractures of the lower extremities, pelvis, and ribs. In addition, the organs within the abdomen are at risk because of a possible third collision. According to the *Journal of Safety Research*, lateral crashes cause approximately 25% of all severe injuries to the aorta and approximately 30% of all fatalities that occur in motor vehicle crashes.⁶

FIGURE 26-12 In a lateral crash, the vehicle is typically struck above its center of gravity and begins to rock away from the side of impact. This causes a type of lateral whiplash in which the passenger's shoulders and head whip toward the intruding vehicle.

© Alexander Gordeyev/Shutterstock.

Rollover Crashes

Certain vehicles, such as large trucks and some sport utility vehicles, are more prone to rollover crashes because of their high center of gravity. Injury patterns that are commonly associated with rollover crashes differ, depending on whether the passenger was restrained or unrestrained. With the potential for multiple impacts on the body, injury patterns are difficult to predict. An unrestrained passenger may have sustained multiple strikes within the interior of the vehicle as it rolled one or more times.

The most common life-threatening event in a rollover is ejection or partial ejection of the passenger from the vehicle (**FIGURE 26-13**). Passengers who have been ejected may have struck the interior of the vehicle many times before ejection and may have also struck objects, such as a tree, a guardrail, or the vehicle's exterior, before landing. Passengers who have been partially ejected may have struck both the interior and exterior of the vehicle and may have been sandwiched between the exterior of the

FIGURE 26-13 Passengers who have been ejected or partially ejected may have struck the interior of the vehicle many times before ejection.

© iStockphoto/Thinkstock/Getty.

vehicle and the environment as the vehicle rolled. Ejection and partial ejection are significant MOIs; in these instances, prepare to care for life-threatening injuries.

Even when restrained, passengers can sustain severe injuries during a rollover crash, although the patterns of injury tend to be more predictable, and when the restraint system is properly used, ejection from the vehicle is prevented. In a rollover, a passenger on the outboard side (the side the vehicle rolls onto) of a vehicle is at high risk for injury because of the centrifugal force (the patient is pinned against the door of the vehicle). When the roof hits the ground during a rollover, a passenger who is restrained can still move far enough toward the roof to make contact and sustain head or a spinal cord injury.

Therefore, rollover crashes are dangerous for both restrained and, to a greater degree, unrestrained passengers because these crashes provide multiple opportunities for second and third collisions. The chance of death increases any time an occupant is ejected from a vehicle.

Rotational Crashes

Rotational crashes (spins) are conceptually similar to rollovers. The rotation of the vehicle as it spins provides opportunities for the vehicle to strike objects such as utility poles. Part of the vehicle stops, while the rest remains in motion. Injuries are the result of a combination of frontal and lateral impacts. For example, as a vehicle spins and strikes a pole, the passengers experience not only the rotational motion but also a lateral impact. Three-point seat belts are effective in preventing injury in angled crashes of up to 45°.

TABLE 26-5 summarizes how to recognize developing problems in trauma patients; many of these apply during vehicle crashes.

Vehicle-Versus-Pedestrian Crashes

In crashes involving pedestrians, there are three phases of impact. Initially the vehicle-pedestrian impact occurs, the pedestrian rotates onto the hood, and then the pedestrian rolls off onto the

TABLE 26-5 Recognizing Developing Problems in Trauma Patients

Mechanism of Injury	Potential Injuries or Conditions	Signs and Symptoms
Blunt or penetrating trauma to the neck	Airway obstruction (from bleeding, secretions, or foreign bodies in upper or lower airway)	- Noisy or labored respirations - Swelling of the face or neck
Substantial chest wall blunt or penetrating trauma	Breathing problems, cardiac or pulmonary contusion, pneumothorax or hemothorax, broken ribs	- Substantial chest pain - Shortness of breath - Asymmetric chest wall movement - Penetrating trauma to the chest
Substantial blunt or penetrating trauma to chest, abdomen, or groin	Hidden blood loss, damage to major vessels	- Bruising, redness, abrasions, or obvious trauma to the abdomen or pelvis - Abdominal distention or rigidity - Tenderness on gentle palpation of the pelvis
Blow to the head (blunt force trauma or fall)	Brain injury	- History of losing consciousness, altered mental status, inability to recall events, combativeness, or changes in speech patterns - Difficulty moving extremities - Severe headache, especially if accompanied by nausea and vomiting
Substantial blunt force trauma, penetrating trauma, or fall from a substantial height	Spinal injury (to bones of the spinal column or spinal cord)	- Severe neck or back pain - Difficulty moving or feeling the extremities - Loss of sensation or tingling in the extremities

ground. The injury pattern depends on the height of the pedestrian and the body area facing the impact.

Vehicle-versus-pedestrian crashes often result in patients who have graphic and apparent injuries, such as broken bones; however, this type of crash can cause serious unseen injuries to underlying body systems. Therefore, you must maintain a high index of suspicion for unseen injuries. A thorough evaluation of the MOI is critical. First, estimate the speed of the vehicle that struck the patient; next, determine whether the patient was thrown by the vehicle, what surface the patient landed on, and at what distance, or whether the patient was struck and pulled under the vehicle. Evaluate the vehicle that struck the patient for structural damage that might indicate contact points with the patient and alert you to potential injuries. Multisystem trauma (multiple traumatic injuries involving more than one body system) is common after this type of event. Consider paramedic backup for any patients who have or are thought to have sustained a significant MOI; paramedic care may be needed for endotracheal intubation or cardiac arrest management.

Special Populations

As a result of smaller body structure and height, pediatric patients generally sustain more injuries to the thoracic and abdominal areas in the initial impact (vehicle impacting person) than do adults. Because their bones are more pliable, maintain a high index of suspicion for underlying organ damage in the absence of fractures.

Vehicle-Versus-Bicycle Crashes

In a vehicle-versus-bicycle collision, evaluate the MOI in much the same manner as vehicle-versus-pedestrian crashes. However, additional evaluation of damage to and the position of the bicycle is warranted. If the patient was wearing a helmet, inspect the helmet for damage and suspect potential injury to the head (**FIGURE 26-14**). Presume that the patient has sustained an injury to the spinal column, or spinal cord, until proven otherwise at the hospital. Initiate and maintain spinal stabilization during the encounter. When practical, roll the patient onto the side to allow for an appropriate assessment to the posterior side of the body.

FIGURE 26-14 If the patient's bike helmet is damaged, suspect head and spine injuries.

© Robert Byron/Dreamstime.com.

Motorcycle Crashes

In 2018, there were 4,985 motorcyclists killed in motor vehicle traffic crashes—38% of whom were not wearing a helmet—and an estimated 82,000 motorcyclists were injured.⁴

Motorcycle collisions are especially dangerous because riders have nothing to help protect them except any protective devices that may be worn—that is, helmet, leather or abrasion-resistant clothing, and boots. There is no structural protection around the rider. Although helmets are designed to protect against impact forces to the head, they do not protect against cervical spine injury. Patients who have experienced a motorcycle crash should undergo cervical spine assessment and have cervical collars placed if indicated. Leather and synthetic gear worn over the body was initially designed to protect professional riders in competition, where falls tend to be controlled and result in long sliding mechanisms on hard surfaces rather than multiple collisions against road objects and other vehicles. Leather clothing protects mostly against road abrasion but offers no protection against blunt trauma from secondary impacts (**FIGURE 26-15**). In a street crash, impacts occur usually against other larger vehicles or stationary objects.

When you are assessing the scene of a motorcycle crash, look for deformity of the motorcycle, the side of most damage, the distance of skid in the road, the deformity of stationary objects or other vehicles, and the extent and location of deformity in the helmet. These findings can be helpful in estimating the extent of trauma in a patient.

FIGURE 26-15 Abrasions from a motorcycle collision.

Courtesy of Rhonda Hunt.

There are four types of motorcycle impacts:

- **Head-on crash.** The motorcycle strikes another object and stops its forward motion while the rider and parts of the motorcycle that are broken off continue their forward motion until stopped by an outside force, such as contact from the road or another opposing force from a secondary crash. Because the motorcycle's center of gravity is above the front axle, there is a forward and upward motion at the point of the impact, causing the rider to go over the handlebars. If the rider's feet remain on the pegs or pedals, then the forward and upward motion of the upper torso is restrained by the legs, producing bilateral femur or tibia fractures and severe foot injuries.
- **Angular crash.** The motorcycle strikes an object or another vehicle at an angle so that the rider sustains direct crushing injuries to the lower extremity between the object and the motorcycle. Trapped legs may be fractured and/or dislocated. This usually results in severe open, comminuted lower extremity injuries with severe neurovascular compromise, often requiring surgical amputation. Traumatic amputations are also common high-speed injuries.

After the initial crush injury to the lower extremity, mechanisms such as those described in a head-on impact also apply. Often, the rider is propelled over the hood of the colliding vehicle. Because the impact is at an angle,

severe thoracoabdominal torsion and lateral bending spine injuries can result, in addition to head injury and pelvic trauma.

- **Ejection.** The rider will travel at high speed until stopped by a stationary object, another vehicle, or contact with the road. Severe abrasion injuries (road rash) down to bone can occur. An unpredictable combination of blunt injuries can occur from secondary crashes.
- **Laying the bike down (also known as a controlled crash).** A technique used to separate the rider from the body of the motorcycle and the object to be hit is referred to as laying the bike down. It was developed by motorcycle racers and adapted by street bikers as a means of achieving a controlled crash. As a collision approaches, the motorcycle is turned flat and tipped sideways at 90° to the direction of travel so that one leg is dropped to the grass or asphalt. This slows the occupant faster than the motorcycle, allowing for the rider to become separated from the motorcycle. If properly protected with leather or synthetic abrasion-resistant gear, injuries should be limited to those sustained by rolling over the pavement and any secondary crash that may occur. When executed properly, this maneuver prevents the rider from being trapped between the bike and the object. However, a rider unable to clear the bike will continue into the vehicle, often with devastating results.

Bicycles and off-road vehicles, such as four-wheelers and snowmobiles, are capable of producing injuries similar to those from motorcycles, with a few differences. Possibly the biggest difference with injuries from off-road vehicles is that reaching the patients is often a challenge. If the traumatic event happens in a remote location, then you must make immediate decisions about issues such as what medical equipment to take to the location and how you will evacuate the patients. Also, in these types of situations patients are often not wearing helmets or other safety equipment that motorcycle riders often employ. Although bicycle riders who are hit by motor vehicles are more likely to be wearing a helmet, they will sustain injuries similar to those found in pedestrians struck by motor vehicles.

Falls

The injury potential of a fall is related to the height from which the patient fell. The greater the height of the fall, the greater the potential for injury. As mentioned earlier, any adult patient who has fallen more than 20 feet (6 m) should be considered at risk for injuries to multiple body systems. Falls from substantial heights are associated with potential for high-energy injury, and patients should be evaluated accordingly.

When falling from a height, the patient lands on the surface just as an unrestrained passenger smashes into the interior of a vehicle. The internal organs travel at the speed of the patient's body before it hits the ground and stop by smashing into the interior of the body. Again, as in a motor vehicle crash, it is these internal injuries that are the least obvious on assessment but pose the gravest threat to life. Therefore, suspect internal injuries in a patient who has fallen from a substantial height, just as you would in a patient who has been in a high-speed motor vehicle crash.

When possible, you should also identify what type of surface the patient landed on and how the patient landed. This information, which may be gleaned from the environment, the patient, and/or bystanders, may help you to predict what areas of the body might be the most seriously injured.

Patients who fall and land on their feet may have less severe internal injuries because their legs

may have absorbed much of the energy of the fall (**FIGURE 26-16**). However, as a result, they may have very serious injuries to the lower extremities and pelvic and spinal injuries from energy that the legs did not absorb.

Patients who fall onto their heads, as in diving accidents, will likely have serious head and/or spinal injuries. In either case, a fall from a substantial height is a serious event with great injury potential, and the patient should be evaluated thoroughly. Take the following factors into account:

- The height of the fall
- The type of surface struck
- The part of the body that hit first, followed by the path of energy displacement
- Area of the body over which the impact is distributed

Special Populations

To evaluate the MOI when your patient is a child, remember this: falls greater than 10 feet (3 m) or two to three times the child's height indicate a significant MOI; injuries to multiple body systems are likely in such cases. Also note that small children are top heavy, so they tend to land on their head even from small falls of a minimal height.

YOU are the Provider

Part 3

As the fire department arrives and begins extrication, you ask the law enforcement officers to establish a landing zone for the helicopter. As you are preparing your airway equipment and intravenous (IV) supplies, you hear your partner yell that the patient has been extricated. You rapidly apply a cervical collar, place her on a long backboard, and move her to the back of the ambulance. Finding inadequate respirations, you place a dual-lumen airway device and instruct your partner to ventilate at the appropriate rate and depth. You quickly establish bilateral IV lines and rapidly infuse the first two 250-mL boluses of normal saline to increase the patient's blood pressure.

Recording Time: 14 Minutes

Respirations	8 breaths/min, shallow; assisted at 12 breaths/min
Pulse	Unobtainable radially; 140 beats/min at carotid artery
Skin	Cool, pale, and clammy
Blood pressure	Unable to obtain via palpation
Oxygen saturation (SpO₂)	Unable to obtain
Pupils	Nonreactive

4. Does this patient meet the criteria for aeromedical evacuation?

FIGURE 26-16 When a patient falls and lands on the feet, the energy is transmitted to the spine, sometimes producing a spine injury in addition to injuries to the legs and pelvis.

© Jones & Bartlett Learning.

Many falls, especially those sustained by older people, are not the result of high-energy trauma, even though broken bones may result. Older patients often have osteoporosis, a condition in which the musculoskeletal system can fail under relatively low stress because the bones are structurally weakened. An older patient with osteoporosis can sustain a fracture as a result of a fall from a standing position. These cases do not constitute high-energy trauma unless the patient fell from a substantial height.

Special Populations

Many geriatric patients are seriously injured from falls. Completely assess the older patient for all possible injuries, even from low-impact falls.

Finally, always consider syncope or other underlying medical causes of the fall. If the patient's condition is stable, attempt to determine exactly

FIGURE 26-17 Injuries from low-energy penetrations, such as a stab wound, are caused by the sharp edges of the object moving through the body.

Courtesy of Andrew N. Pollak, MD, FAAOS.

what happened to cause the fall; did the person simply slip and fall or have a syncopal episode and then fall?

Penetrating Trauma

Penetrating trauma can be classified as low, medium, or high energy. Low-energy penetrating trauma may be caused accidentally by impalement or intentionally by a knife, ice pick, or other weapon (**FIGURE 26-17**). According to the CDC, 39,740 Americans were killed by firearms in 2018.⁷

Penetrating trauma, often the result of a gunshot or stab injury, is difficult to assess because there is often little external evidence of the actual damage. The amount of force that is applied to the body in a gunshot wound is most directly related to the caliber of the weapon, the velocity of the projectile, and the distance of the weapon from the patient when it was fired. Point-blank and high-velocity gunshot wounds result in more significant injuries. By comparison, the force that is exerted on the patient in stab injuries is minimal, even though these injuries can still be lethal.

In some penetrating wounds, such as stab wounds, the body area that is involved can be estimated by looking at the location of entrance and the length of the weapon, if known. However, angle or direction of travel is also pertinent. In gunshot wounds, the internal organs that are injured may have no relationship to the **entrance wound** and the **exit wound**, if these wounds exist (**FIGURE 26-18**). Bullets may bounce off bones or dense organs in

FIGURE 26-18 Entrance and exit wounds in the leg from a low-velocity gunshot wound.

© E.M. Singletary, M.D. Used with permission.

the body, making the exact path almost impossible to determine. Some bullets are designed to tumble, flatten out, break apart, ricochet, or “mushroom” after they enter the body.

When assessing a patient with a penetrating injury, first determine the number of penetrating injuries, and then combine that information with what you know about the potential pathway of penetrating projectiles to form an index of suspicion about unseen life-threatening injuries. Remember that you can only *estimate* the extent of the injury. For example, in some cases of assault, an assailant may have moved the weapon in a back-and-forth motion after it entered the patient.

Gunshot Wounds

The path the projectile takes is referred to as a **trajectory**. Fragmentation, especially frangible bullets that are designed to disintegrate into tiny particles on impact, will increase damage as multiple fragments increase the likelihood of multiple organs/vessels sustaining injury. Hollow point bullets expand as they enter the target in order to decrease penetration and cause more tissue damage. Full metal jacket bullets cause less damage than fragmented rounds because of their tendency to pass through the body's tissues. The bullet's speed is a major factor in the resulting injury pattern; there is often additional damage caused by the object moving inside the body but not along the suspected pathway. This phenomenon, called **cavitation**, which results from the rapid changes in tissue and fluid pressure

FIGURE 26-19 There are two types of cavitations: temporary and permanent.

© Jones & Bartlett Learning.

FIGURE 26-20 The area damaged by high-velocity projectiles such as bullets can be many times larger than the diameter of the projectile itself.

© Charles Stewart MD, EMDM MPH.

that occur with the passage of the projectile, can result in serious injury to internal organs distant to the actual path of the bullet (**FIGURE 26-19**). A temporary cavity is produced by stretching the tissue surrounding the point of impact. Permanent cavitation injury results closer to the bullet path where the pressure fluctuations are greatest and remains after the projectile has passed through the tissue.

The relationship between distance and severity of injury varies depending on the type of weapon involved, such as a rifle, pistol, or shotgun. Air resistance, often referred to as **drag**, slows the projectile, decreasing the depth of penetration and energy of the projectile and thus reducing tissue damage. Much like a boat moving through water, the bullet disrupts not only the tissues that are directly in its path but also those in its wake. Therefore, the area that is damaged by medium- and high-velocity projectiles is typically many times larger than the diameter of the projectile itself (**FIGURE 26-20**). This is one reason that exit wounds are often, but not always, much larger than entrance wounds. You must

remain alert during assessment because patients will exhibit various signs and symptoms depending on the organ or organs struck.

As with motor vehicle crashes, the energy available for a bullet to cause damage is more a function of its speed than its mass (weight). If the mass of the bullet is doubled, the energy that is available to cause injury is doubled. If the speed (velocity) of the bullet is doubled, the energy that is available to cause injury is quadrupled. For this reason, it is important for you to try to determine the type of weapon that was used. Although it is not necessary (or always possible) for you to distinguish between medium- and high-velocity injuries, any information regarding the type of weapon that was used should be relayed to medical control. Police at the scene may be a useful source of information regarding the caliber and type of weapon. Organs injured in a gunshot wound vary depending on the pathway of the projectile. There is an entrance wound, and, if the bullet goes completely through, an exit wound. The entrance wound is characterized by a round or oval hole that is crushed inward. The rim is usually 1 to 2 mm wide and dark because of the grease or other substance on the bullet. There may be an abrasion produced by the spinning of the bullet. The size of the abrasion depends on the contact with the skin. It will be larger when the impact is at an angle. If the end of the weapon is within 4 to 6 inches from the skin, there may also be burns from the flame emitted from the barrel. In contrast, the exit wound is pushed outward and, rather than being round, may be stellate (star-shaped) or a slit.

Words of Wisdom

A blunt object that contacts minimal surface area (such as a wooden dowel compressed against the forearm) creates damage that is similar to that of penetrating trauma but without breaking the skin.

Blast Injuries

Although most commonly associated with military conflict, **blast injuries** are also seen in civilian practice in industrial settings such as mines, shipyards, and chemical plants and, increasingly, in association with terrorist activities. They are also more

common today owing to the increased use of explosives as a tool for urban terrorism and, in the United States, from methamphetamine laboratory explosions. Although civilian explosions in an industrial or mining setting used to be mostly characterized by blast injuries and burns, terrorist bombs often contain shrapnel. As an AEMT, you and other emergency medical services (EMS) and trauma services personnel should be fully educated and aware of what to expect in these scenarios. People who are injured in explosions may be injured by any of five different mechanisms, often causing multisystem trauma (**FIGURE 26-21**).

Categories of Blast Injuries

Primary Blast Injuries

Primary blast injuries are due entirely to the blast itself—that is, damage to the body caused by the pressure wave generated by the explosion. When an explosion occurs, a pressure wave rapidly develops; this tremendous, concentrated pressure results from air displacement and heat originating from the center of the blast. **Flash burns** are also considered part of the primary injury pattern (in addition to the overpressure). The organs generally affected by primary blast effects are the lungs, eardrums, and other compressible structures. The pressure wave damages air-filled cavities.

Proximity to the origin of the pressure wave is associated with a high risk of injury or death. Explosions from a bomb start at the center and move outward, so people closer to the device will be affected more. Explosions from fumes or dust involve an entire area, so there is no “safe” region. Underwater blasts have a threefold greater range because of the near-incompressibility of water. Explosions that occur within a confined space result in more force applied to the body.

Secondary Blast Injuries

Secondary blast injuries result from being struck by flying debris (such as shrapnel from the device or from glass or splinters) that has been set in motion by the explosion. Objects are propelled by the force of the blast and strike the person, causing injury. These objects can travel great distances and can be propelled at tremendous speeds, up to almost 3,000 mph for conventional military explosives.

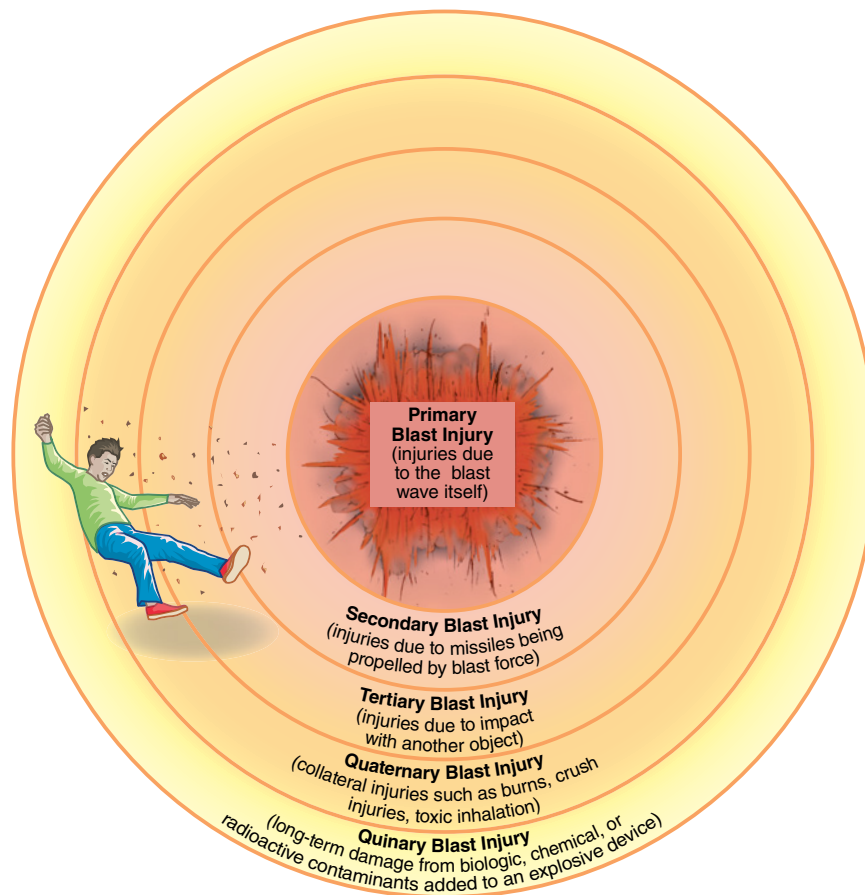

FIGURE 26-21 Mechanisms of blast injuries.

© Jones & Bartlett Learning.

A blast wind occurs as the shock wave applies force to air molecules. Although less forceful than the pressure wave, the blast wind is longer lasting and can hurl projectiles at high velocities. Projectiles present serious hazards. Flying debris may cause blunt and penetrating injuries. With bombs, the casing fragments rip apart with monumental force, spreading in all directions. Structural elements can break apart and travel at high rates of speed. Nails, wood splinters, and glass shards can impale people located near the blast.

Tertiary Blast Injuries

Tertiary blast injuries occur when a person is hurled by the force of the explosion (or blast wind) against stationary, rigid objects, such as the ground or walls. Physical displacement of the body is also referred to as ground shock when the body impacts the ground. The injuries that result are numerous and result from both blunt and penetrating

mechanisms. A blast wind also causes the patient's body to be hurled or thrown, causing further injury.

Quaternary (Miscellaneous) Blast Injuries

Quaternary injuries result from the miscellaneous events that occur during an explosion. For example, the heat generated during an explosion may cause burns, ranging from superficial flash burns to full-thickness burns involving the entire or large areas of the body. These injuries can include burns from hot gases or fires started by the blast, respiratory injury from inhaling toxic gases, and crush injury from the collapse of buildings. There is also a risk for entrapment that may be prolonged for days.

Quinary Blast Injuries

Quinary blast injuries are caused by biologic, chemical, or radioactive contaminants that have been

added to a traditional explosive device. The initial explosion disperses these materials, causing additional long-term damage through biologic, chemical, or radioactive mechanisms. This type of blast injury is associated with “dirty bombs” and is of increased concern because of the threat of its use by terrorist organizations.

Most patients who survive an explosion will have some combination of the types of injuries mentioned. The discussion here will be confined to primary blast injuries because these injuries are the ones that are most easily overlooked.

Tissues at Risk

Organs that contain air, such as the middle ear, lung, and gastrointestinal tract, are most susceptible to barotrauma. The ear is the organ system that is most sensitive to blast injuries. The **tympanic membrane** evolved to detect minor changes in pressure and will rupture at pressures of 5 to 7 pounds per square inch above atmospheric pressure. Thus, the tympanic membranes are a sensitive indicator that you can use to help determine the possible presence of other blast injuries. The patient may report ringing in the ears, pain in the ears, or some loss of hearing, and blood may be visible in the ear canal. Dislocation of structural components of the ear, such as the ossicles conforming the inner ear, may occur. Permanent hearing loss is possible. These findings can be used to assist in triaging patients as they indicate risk of pressure injuries to the lungs.

Pulmonary blast injuries are defined as pulmonary trauma (consisting of contusions and hemorrhages) that results from short-range exposure to the detonation of explosives. When the explosion occurs in an open area, the patient's side that was toward the explosion is usually injured, but the injury can be bilateral when the victim is in a confined space. Primary blast injury is often characterized by a lack of external visible injuries and thus can go unrecognized. The patient may report tightness or pain in the chest and may cough up blood and have tachypnea or other signs of respiratory distress. Subcutaneous emphysema (crackling under the skin) can be detected over the chest using palpation, indicating air in the thorax. Pneumothorax is a common injury and may require emergency decompression in the field by paramedics for your patient to survive if tension

develops. Pulmonary edema may ensue rapidly. If there is any reason to suspect lung injury in a blast victim (even just the presence of a ruptured eardrum), administer oxygen. Avoid giving oxygen under positive pressure, however (that is, by demand valve) because that may simply increase the damage to the lung. Be cautious as well with IV fluids, which may be poorly tolerated in patients with this type of lung injury and result in pulmonary edema. More information on pulmonary injuries, including pneumothorax, can be found in Chapter 31, *Chest Injuries*.

One of the most concerning pulmonary blast injuries is **arterial air embolism**, which occurs on alveolar disruption with subsequent air embolization into the pulmonary vasculature. Even small air bubbles can enter a coronary artery and cause myocardial injury. Air embolisms to the cerebrovascular system can produce disturbances in vision, changes in behavior, changes in level of consciousness, and a variety of other neurologic signs.

Solid organs are relatively protected from shock wave injury but may be injured by secondary missiles or a hurled body. **Petechiae** (pinpoint hemorrhages on the skin) to large hematomas are the dominant forms of pathology. Hollow organs, however, may be injured by similar mechanisms as for lung tissue. Perforation or rupture of the bowel and colon is possible. Underwater explosions result in the most severe abdominal injuries.

Neurologic injuries and head trauma are the most common causes of death from blast injuries. Concussion, intracerebral bleeding, or air embolism may occur. Bradycardia and hypotension are common after an intense pressure wave from an explosion.

Extremity injuries, including traumatic amputations, are common. Patients with traumatic amputation by postblast wind are likely to sustain fatal injuries secondary to the blast. In the global war on terrorism, improved body armor has increased the number of survivors of blast injuries from shrapnel wounds to the torso. However, the number of severe orthopaedic and extremity injuries has increased. In addition, whereas body armor may limit or prevent shrapnel from entering the body, it also catches more energy from the blast wave, possibly resulting in the victim's being thrown backward, thus increasing the potential for spine and spinal cord injury.

Multisystem Trauma

Multisystem trauma refers to the injuries of a person who has been subjected to multiple traumatic injuries involving more than one body system such as head and spinal trauma, chest and abdominal trauma, or chest and multiple extremity trauma. You must recognize patients who fit into this classification, provide rapid treatment and transportation, and alert medical control as to the nature of the patient's injuries so that the trauma center is prepared prior to your arrival. Multisystem trauma patients have high morbidity and mortality; therefore, they require teams of physicians to treat their injuries. These teams may include specialists such as neurosurgeons, thoracic surgeons, and orthopaedic surgeons.

Words of Wisdom

Although the prospect of assessing and treating a multisystem trauma patient may be daunting for a new AEMT, the course of care remains the same for all. Remain calm, control any major hemorrhage, and manage the ABCs (airway, breathing, and circulation). If you lose focus of what to do next, go back to the basics and reassess ABCs.

Golden Principles of Prehospital Trauma Care

As with any EMS call, your main priority in managing multisystem trauma is to ensure your safety, the safety of your crew, and the safety of the patient. Next, you must determine the need for additional personnel or equipment, evaluate the MOI, and identify and appropriately manage life threats. After these steps have been completed, you can focus on patient care. Begin by assessing and managing the airway, including ventilatory support and oxygen as indicated, while maintaining cervical spine stabilization. Ensure that basic shock therapy, such as controlling hemorrhages, stopping arterial bleeding, and keeping the patient warm, is completed. If bleeding cannot be controlled rapidly by direct pressure, consider the use of a tourniquet. If the patient is bleeding profusely, this must be controlled to ensure sufficient perfusion of organs and tissues.

Safety

Personal safety and the safety of your partner are primary. You cannot provide care for a patient if you are injured. Always carefully assess the environment from the ambulance as you are approaching the scene, and continue to survey the scene as you approach the patient. A scene is dynamic; it has the potential to change continually, and you must be aware to protect yourself. Watch for passing vehicles who may be rubbernecking, scene hazards, hostile environments, suspicious items or people, unsecured crime scenes, and suicidal patients who may become homicidal.

After threats to the ABCs are corrected, rapidly proceed with spinal immobilization if indicated. If the patient is trapped, consider the use of rapid extrication techniques. In most patients with multisystem trauma, definitive care requires surgical intervention; therefore, on-scene time should be limited to 10 minutes or less. This is referred to as the platinum 10 minutes. During transport, obtain a SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history, and complete a secondary assessment. Most care can be provided in transport. However, keep in mind that your patient has sustained multisystem trauma, and the order in which you usually provide treatment and care may need to be adjusted depending on the needs of the patient, including maintaining a patent airway, ensuring adequate ventilation, and controlling hemorrhage. For critically injured patients, consider paramedic intercept and/or air medical transportation. Regardless of the mode of transport, ensure that the patient is transported to an appropriate facility and that the facility is notified as soon as possible. Specific standards of care regarding multisystem trauma will be addressed in detail in different chapters.

Words of Wisdom

Rapid transport decisions are needed for patients who have sustained substantial trauma. After the first 60 minutes, the body has increasing difficulty in compensating for shock and traumatic injuries. This is referred to as the Golden Hour. Because many injured patients require definitive care in less than 1 hour, this is also referred to as the Golden Period.

Words of Wisdom

Do not develop tunnel vision as you are approaching a scene. You may feel drawn to a screaming patient entrapped in a vehicle, but rushing toward a scene can result in potential injury to you if the scene is not safe. Also, gross injuries may not be life threatening. Occult injuries, such as closed chest or abdominal trauma, may have the potential for greater mortality than isolated extremity injuries.

Patient Assessment

Identifying life-threatening illnesses and injuries as soon as possible improves patient outcomes. As an AEMT, you must apply this knowledge as well as the appropriate assessment skills to assess, triage, treat, and transport patients with traumatic injuries to the most appropriate facility. The major components of patient assessment include the following:

- Scene size-up
- Primary survey
- History taking
- Secondary assessment
- Reassessment

When assessing a patient with trauma, follow the XABCDE mnemonic (eXsanguinating hemorrhage, Airway, Breathing, Circulation, Disability, and Exposure). This mnemonic adds the letter *X* to the ABCDE mnemonic for assessment. *X* represents the importance of looking for severe, exsanguinating hemorrhage first. Such hemorrhage can be addressed quickly when it is coming from an extremity. Failure to address it quickly will result in loss of total blood volume and rapid progression to death.

When you are caring for a patient who has experienced a significant MOI and is considered to be in serious or critical condition, you should perform a rapid physical examination. Any patient who has sustained a nonsignificant MOI should receive an assessment focused on the chief complaint. The human body is divided into areas (or systems) based on body function, and its internal organs are subject to unseen injuries when force is applied to the body. For example, the brain may have bruising, the heart and lungs may have bruising or unseen bleeding, and the organs of the abdomen may have life-threatening bleeding. The following sections discuss the assessment of various body systems.

YOU are the Provider

Part 4

While you are performing your assessment of the patient, the flight crew calls you on the radio advising that they are 10 minutes from touchdown on the scene. You acknowledge the transmission and focus on your assessment. As you are assessing the neck, you note a crackling sound on the lower portion of the neck when you palpate. Your examination findings of the chest are unremarkable, but when you palpate the abdomen, you find it rigid and distended. As you are completing the remainder of your exam, the flight crew touches down and steps into your ambulance. You provide a quick report and assist them in preparing the patient for flight. Approximately 5 minutes later, the patient is airborne, on her way to the local trauma center.

Recording Time: 20 Minutes

Respirations	Assisted at 12 breaths/min
Pulse	120 beats/min at carotid artery, weak radially
Skin	Cool, pale, and clammy
Blood pressure	Unobtainable
Oxygen saturation (SpO₂)	Unobtainable
Pupils	Nonreactive

5. What is the crackling sound heard on the neck, and how is it caused?
6. Now that the critical patient has departed the scene, what should you do with the deceased patient?

Documentation and Communication

Provide thorough documentation of the scene as well as patient assessment and care. As a prehospital provider, you are the eyes and ears of the physician. You must paint a picture for the providers who will assume care at the hospital for them to maintain an appropriate index of suspicion for the patient. Cameras provide an invaluable wealth of information for trauma surgeons, but patient care must not be delayed to take photos. Kinematics of trauma along with mechanisms of injury are important for trauma teams. Also remember to frequently reassess and document vital signs. Trending can be vital to direct appropriate patient care.

Injuries to the Head

The brain lies well protected within the skull. However, when the head is injured from trauma, disability and unseen injury to the brain may occur. The brain itself, or the blood vessels around it, may tear or become bruised, causing bleeding. Bleeding or swelling inside the skull from brain injury is often life threatening; therefore, your assessment must include conducting frequent neurologic examinations. Neurologic assessments coupled with the patient's level of consciousness will often provide details on subtle changes in the patient's condition. Some patients will not have obvious signs or symptoms, such as changes in pupillary size and reactivity, of unseen brain injury until minutes or hours after the injury has occurred.

Injuries to the Neck and Throat

The neck and throat contain many structures that are susceptible to injuries from trauma that could be serious or deadly to your patients. In this region of the human body, the trachea (or windpipe) may become torn or swell after an injury to the neck or deviate after an injury to the lungs. These types of injuries may result in an airway problem that could quickly become a serious life threat because they interfere with the patient's ability to breathe; therefore, your assessment must include frequent physical examination looking for Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, Swelling (DCAP-BTLS) in

the neck region. In addition, you should assess for jugular venous distention and tracheal deviation (late sign of injury).

The neck also contains large blood vessels that supply the brain with oxygen-rich blood. When a neck injury occurs, swelling may prevent blood flow to the brain and cause injury to the central nervous system, even though the brain may not have been directly affected by the initial force that caused the injury to the neck. If a penetrating injury to the neck results in an open wound, the patient may have substantial bleeding, or air may be drawn into the circulatory system, resulting in an air embolism. Always use an occlusive dressing on any open neck wound. A crushing injury to the upper part of the neck may cause the cartilage of the upper airway and larynx to fracture. This can result in the leakage of air into the soft tissue of the neck. When air is trapped in subcutaneous tissue (subcutaneous emphysema), it produces a crackling feeling when palpated, called subcutaneous crepitation. Either air in the circulation or an airway cartilage fracture may cause rapid death.

Injuries to the Chest

The chest contains the heart, the lungs, and the large blood vessels of the body. When injury occurs to this area of the body, many life-threatening injuries may occur. For example, blunt trauma to the chest can fracture ribs or the sternum. When ribs are broken and the chest wall does not expand normally during breathing, this interferes with the body's ability to obtain sufficient amounts of oxygen for the cells. Bruising may occur to the heart and cause an irregular heartbeat. Depending on the severity of the trauma, the large vessels of the heart may be torn inside the chest and cause massive unseen bleeding that can quickly kill the trauma patient. In some chest injuries the lungs become bruised, thus interfering with normal oxygen exchange in the body.

Some chest injuries result in air collecting between the lung tissue and the chest wall. As air accumulates in this space, the lung tissue becomes compressed, again interfering with the body's ability to effectively exchange oxygen. This injury is called a pneumothorax. If left untreated or unrecognized, the lung tissue becomes squeezed under pressure until the heart is also squeezed, preventing a return of venous blood and thereby reducing preload. This

condition is called a tension pneumothorax and is a life-threatening emergency. Bleeding develops in some patients in this portion of the chest. Instead of air collecting in this space, blood collects here and causes interference with breathing. This condition is called a hemothorax, and it also poses a threat to the patient's life.

A penetration or perforation of the integrity of the chest is called an open chest wound. As air enters the chest cavity, the natural pressure balance within the chest cavity is no longer equal. If left untreated, shock and/or death will result. Regardless of the particular injury, it is imperative that you reassess a trauma patient's chest region every 5 minutes. The assessment should include DCAP-BTLS, breath sounds, and chest rise and fall. Some patients will not have immediately obvious signs or symptoms such as absent breath sounds or respiratory difficulty.

Injuries to the Abdomen

The abdomen is an area of the human body that contains many organs vital to body function. These organs also require a high amount of blood flow so they can perform the functions necessary for life. Recall that the organs of the abdomen and retroperitoneum (the space immediately behind the true abdomen) can be classified into two simple categories: solid and hollow. The solid organs include the liver, spleen, pancreas, and kidneys. The hollow organs include the stomach, large and small intestines, and urinary bladder.

When injuries from trauma occur in this region of the body, serious and life-threatening problems may occur. The solid organs may tear, lacerate, or fracture. This causes serious bleeding into the abdomen that can quickly cause death. Be alert for a trauma patient who reports abdominal pain—it may be a symptom of abdominal bleeding. Also be alert to vital signs that begin to worsen; this can be a sign of serious, unseen bleeding inside the abdomen.

When the hollow organs of the body have been injured, they may rupture and leak toxic chemicals used for digestion into the abdomen. This not only causes pain, because the contents of the intestines are not sterile, but the patient also may eventually develop a life-threatening infection.

The abdomen also contains large blood vessels that supply the organs of this region and the lower

extremities with oxygen-rich blood. Occasionally these vessels rupture or tear and cause serious unseen bleeding that may result in death. Some patients, particularly healthy young adults, are able to compensate longer than others for blood loss; therefore, you should always maintain a high index of suspicion when the MOI suggests injury to the abdominal region. This is best accomplished by reassessing the abdominal region using DCAP-BTLS.

Management: Transport and Destination

Caring for victims of traumatic injuries requires you to have a solid understanding of the trauma system in the United States. You need to have a good working knowledge of the resources available to you, including the most optimal methods of rapid transport and trauma centers that can best provide definitive care.

Trauma Lethal Triad

Research has identified what has been termed the **trauma lethal triad** of hypothermia, coagulopathy (poor blood clotting), and acidosis as a major contributor to death in patients with severe traumatic bleeding⁸ (FIGURE 26-22). It has been well documented that even mildly hypothermic patients have a lower survival rate than normothermic patients. In addition, hypothermia contributes to coagulopathy, which also reduces survival from traumatic bleeding (if the blood cannot clot, the body cannot stop the bleeding). Any factor that interferes with blood clotting will cause more blood loss in the patient than would otherwise occur. This will result in

FIGURE 26-22 The trauma lethal triad.

© Jones & Bartlett Learning.

poor perfusion and ultimately, death. Finally, acidosis (defined as a blood pH of less than 7.35) often occurs with excessive bleeding and treatments to compensate for it. For example, normal saline, which is commonly administered via IV bolus to treat hypotension, is acidic and can increase acidosis. Acidosis contributes to coagulopathy and complicates treatment of these patients.

How should knowledge of this lethal triad of conditions affect your treatment of trauma patients? First, you need to aggressively seek to control all bleeding to the best of your ability. Do not hesitate to use a tourniquet to stop bleeding from an extremity. Next, keep your patients warm; place blankets under them as well as on top of them, and ensure IV fluids are warmed to at least normal body temperature. Finally, minimize the volume of acidic IV fluid you administer to prevent interfering with coagulation and contributing to acidosis. If possible, monitor end-tidal carbon dioxide and ventilations to prevent respiratory acidosis, and consider calling for paramedic backup for administration of tranexamic acid, a medication that can help control internal bleeding, if local protocols allow and transport times to a trauma center may be prolonged.

Scene Time

Because survival of critically injured trauma patients is time dependent, limit on-scene time to the minimum amount necessary to correct life-threatening injuries and package the patient. As mentioned, on-scene time for critically injured patients should ideally be less than 10 minutes—the platinum 10. The following criteria will help you identify a critically injured patient:

- Dangerous MOI
- Decreased level of consciousness
- Any threats to airway, breathing, or circulation

Patients who present with these criteria or who are very young or old or who have chronic illnesses should also be considered high risk, thus requiring rapid treatment and transport.

Type of Transport

Modes of transport ultimately come in one of two categories: ground or air. When making the decision to transport by ground, several factors should

FIGURE 26-23 A helicopter may be used to transport patients quickly to a trauma center.

Courtesy of Mark Woolcock.

be taken into consideration. Can the appropriate facility be reached within a reasonable time frame by ground transport? Ground transportation EMS units are generally staffed by emergency medical technicians, AEMTs, and paramedics. Air transportation EMS units or critical care transport units are generally staffed by critical care transport professionals such as critical care nurses and paramedics (**FIGURE 26-23**). What is the extent of injuries? If you are in a congested area, can the patient be transported to a more accessible landing zone for air medical transport? Transport modes are discussed in Chapter 16, *Medical Overview*.

You should be familiar with your local protocols defining indications for use of air medical transport. The Association of Air Medical Services (AAMS) and MedEvac Foundation International identify the following criteria in the white paper, *Air Medicine: Accessing the Future of Healthcare*, for the appropriate use of emergency air medical services for trauma patients:

- There is an extended period required to access or extricate a remote (eg, injured hiker, snowmobiler, or boater) or trapped patient (eg, in a crashed vehicle) that depletes the time frame to get the patient to the trauma center by ground.
- Distance to the trauma center is greater than 20 to 25 miles.
- The patient needs medical care and stabilization at the advanced life support (ALS) level, and there is no ALS-level ground ambulance service available within a reasonable time frame.

- Traffic conditions or hospital availability make it unlikely that the patient will get to a trauma center via ground ambulance within the ideal time frame for best clinical outcome.
- There are multiple patients who will overwhelm resources at the trauma centers reachable by ground within the time frame.
- EMS systems require patients to be brought to the nearest hospital for initial evaluation and stabilization, rather than bypassing those facilities and going directly to a trauma center. This may add delay to definitive surgical care and necessitate air transport to mitigate the effect of that delay.
- There is a multiple-casualty incident.

These recommendations serve as a guideline for local decision makers to develop more comprehensive protocols for the use of air medical transport. You should always follow your local protocols when determining what type of patient transportation is appropriate.

Destination Selection

You will often be summoned to accident scenes to transport critically ill trauma patients to definitive care. Before you even get to the scene, you should know the criteria for referral to a trauma center and what hospital resources are available in your area. It is important to transport your trauma patient to the most appropriate facility based on the injuries. The National Study on the Costs and Outcomes of Trauma reported a 25% decrease in mortality for severely injured adult patients who received care at a Level I trauma center compared with those treated at a lower-level trauma center.⁹ Trauma centers are classified into Levels I through IV, with Level I having the most resources followed by Levels II, III, and IV (**TABLE 26-6**).

A Level I facility is a regional resource center and generally serves large cities or heavily populated areas. Level I facilities must be capable of providing every aspect of trauma care from prevention through rehabilitation; therefore, the facility must have adequate personnel and resources. Because of the extensive requirements, most Level I facilities are university-based teaching hospitals.

A Level II facility is typically located in areas of lower population density. Level II centers are expected to provide initial definitive care, regardless

of injury severity. These facilities can be academic institutions or a public/private community facility. Because of its location and resources, a Level II trauma center may not be able to provide the same comprehensive care as a Level I trauma center. The major difference between Level I and Level II facilities is that the latter typically lack the same level of programmatic focus on trauma research and trauma prevention.

Level III facilities serve communities that do not have access to Level I or II facilities. Level III facilities provide assessment, resuscitation, emergency care, and stabilization. A Level III facility must have transfer agreements with a Level I or II trauma center and must have protocols in place to transfer patients whose needs exceed the resources of the facility.

Level IV facilities are typically found in remote outlying areas where no higher level of care is available. These facilities provide advanced trauma life support prior to transfer to a higher-level trauma center. Such a facility may be a clinic urgent care facility, with or without a physician.

Although an inclusive trauma system should leave no facility without a direct link to a Level I or II facility, all facilities are expected to provide the same high quality of initial care regardless of the classification level.

Trauma centers are categorized as either adult trauma centers or pediatric trauma centers, but not necessarily both. Pediatric trauma centers are not nearly as common as adult trauma centers. When transporting a pediatric trauma patient, you must be certain to transport your patient to a pediatric trauma center if there is one in your area; do not make the mistake of transporting a pediatric patient to an adult trauma center when a pediatric trauma center is available.

Words of Wisdom

Because traumatic injuries are as varied as the mechanisms that cause them, it is almost impossible for you to prepare for every possible situation that you may face during your career. In all situations, you must remain calm, complete an organized assessment, correct life-threatening injuries, and do no harm. You should never hesitate to contact paramedic backup or medical control for guidance.

TABLE 26-6 Key Elements for Trauma Centers

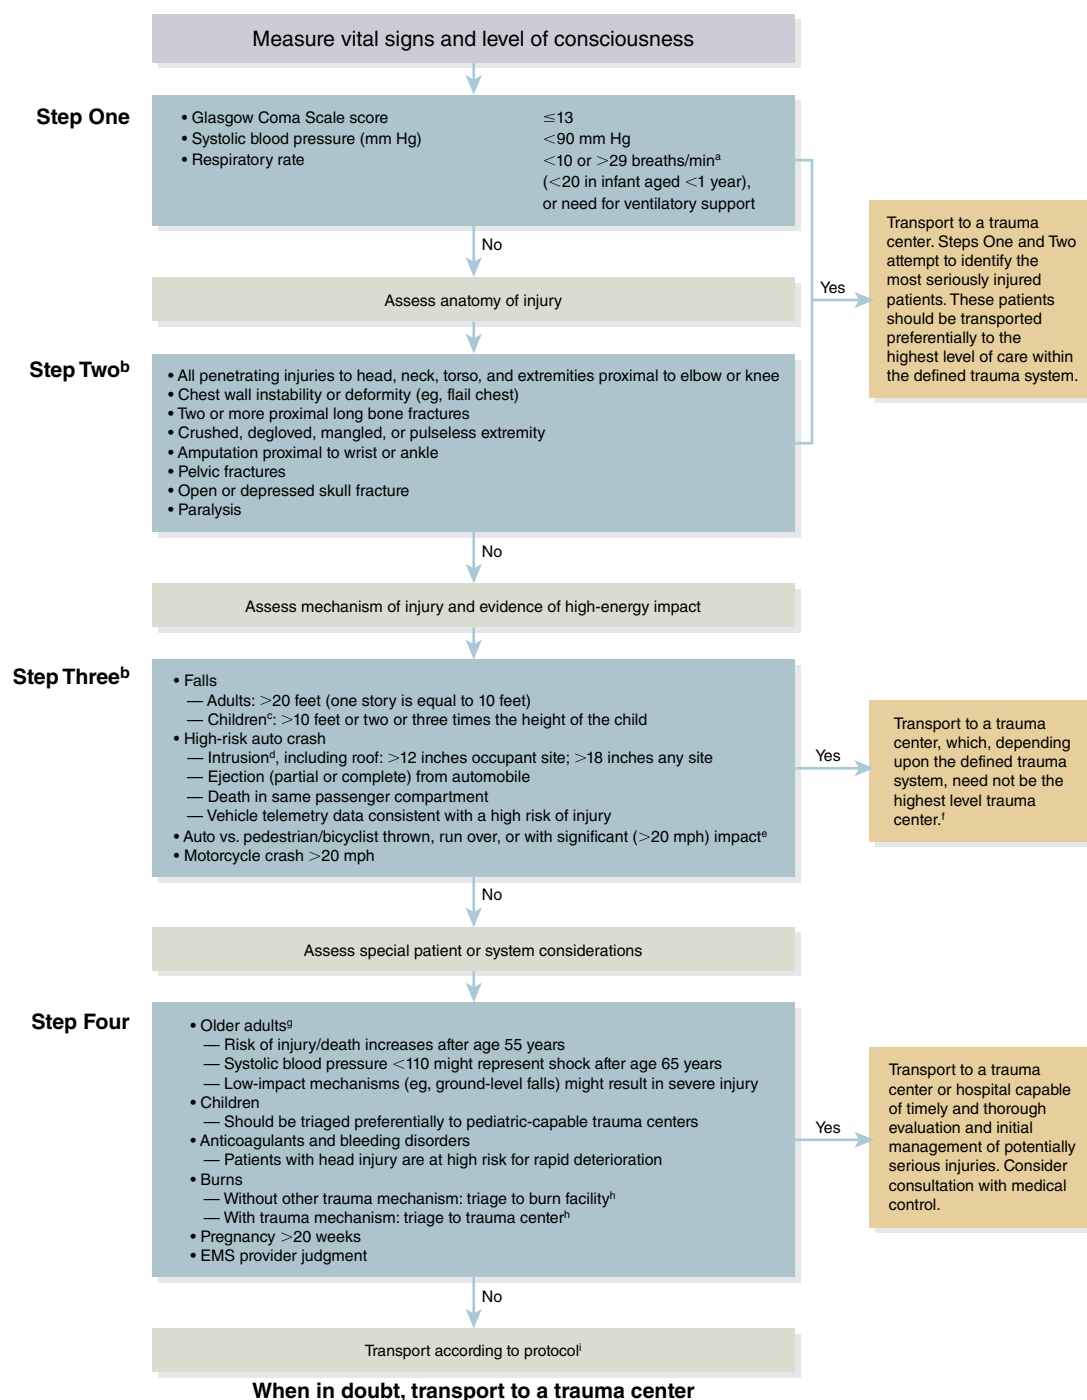

Level	Definition	Key Elements
Level I	A comprehensive regional resource that is a tertiary care facility; capable of providing total care for every aspect of injury—from prevention through rehabilitation	1. 24-hour in-house coverage by general surgeons 2. Availability of care in specialties such as orthopaedic surgery, neurosurgery, anesthesiology, emergency medicine, radiology, internal medicine, and critical care 3. Should also include cardiac, hand, pediatric, and microvascular surgery and hemodialysis 4. Provides leadership in prevention, public education, and continuing education of trauma team members 5. Committed to continued improvement through a comprehensive quality assessment program and organized research to help direct new innovations in trauma care
Level II	Able to initiate definitive care for all injured patients	1. 24-hour immediate coverage by general surgeons 2. Availability of orthopaedic surgery, neurosurgery, anesthesiology, emergency medicine, radiology, and critical care 3. Tertiary care needs such as cardiac surgery, hemodialysis, and microvascular surgery may be referred to a Level I trauma center 4. Committed to trauma prevention and continuing education of trauma team members 5. Provides continued improvement in trauma care through a comprehensive quality assessment program
Level III	Ability to provide prompt assessment, resuscitation, and stabilization of injured patients and emergency operations	1. 24-hour immediate coverage by emergency medicine physicians and prompt availability of general surgeons and anesthesiologists 2. Program dedicated to continued improvement in trauma care through a comprehensive quality assessment program 3. Has developed transfer agreements for patients requiring more comprehensive care at a Level I or Level II trauma center 4. Committed to continuing education of nursing and allied health personnel or the trauma team 5. Must be involved with prevention and have an active outreach program for its referring communities
Level IV	Ability to provide ATLS before transfer of patients to a higher-level trauma center	1. Includes basic ED facilities to implement ATLS protocols and 24-hour laboratory coverage 2. Transfer to higher-level trauma centers follows the guidelines outlined in formal transfer agreements 3. Committed to continued improvement of these trauma care activities through a formal quality assessment program 4. Involved in prevention, outreach, and education within its community

Abbreviations: ATLS, Advanced Trauma Life Support; ED, emergency department

Data from: American College of Surgeons Committee on Trauma. *Resources for Optimal Care of the Injured Patient*. Chicago, IL: American College of Surgeons; 2014.

It is important for you to be familiar with how the American College of Surgeons Committee on Trauma (ACS-COT) classifies trauma care. In 2011, the ACS-COT and the CDC published an updated field triage decision scheme (**FIGURE 26-24**). These criteria are intended to help prehospital

care providers recognize injured patients who are likely to benefit from transport to a trauma center compared with transport to an emergency department. It is not intended as a mass-casualty or disaster triage tool; it is only intended for individual patients.

Abbreviation: EMS, emergency medical services

^a The upper limit of respiratory rate in infants is > 29 breaths per minute to maintain a higher level of overtriage for infants.

^b Any injury noted in Step Two or mechanism identified in Step Three triggers a "yes" response.

^c Age < 15 years.

^d Intrusion refers to interior compartment intrusion, as opposed to deformation which refers to exterior damage.

^e Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact > 20 mph with a motor vehicle.

^f Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system; need not be the highest-level trauma center.

^g Age > 55 years.

^h Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

ⁱ Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.

FIGURE 26-24 2011 decision scheme for field triage of injured patients.

Data from: Centers for Disease Control and Prevention. Guidelines for field triage of injured patients: recommendations of the national expert panel on field triage, 2011. *Morbidity and Mortality Weekly Report (MMWR)*, January 13, 2012.

Words of Wisdom

It is imperative that you have a strong understanding of trauma scoring systems to appropriately classify patients. The **trauma score** calculates a number from 1 to 16, with 16 being the best possible score. It accounts for the GCS score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill. The GCS is an evaluation tool used to determine level of consciousness, which evaluates and assigns point values (scores) for eye opening, verbal response, and motor response; these scores are then totaled and help to effectively predict patient outcomes. Note that the lower the score, the more severe the extent of brain injury. The trauma score relates to the likelihood of patient survival. However, this scoring system does not accurately predict survivability in patients with severe head injuries because motor and verbal deficits make those criteria difficult to assess; in its place, the Revised Trauma Score, discussed next, is used. (See Chapter 10, *Patient Assessment*, for the GCS.)

Revised Trauma Score

The numeric scoring of trauma patients for determining the severity of their injury is common practice in the

health care profession. When the various scoring systems were created, it was thought that the implementation of the scoring system would assist in rapidly identifying the severity of the patient's injuries. There are several different trauma scoring systems. The one that is the most commonly used for patients with head trauma is the **Revised Trauma Score (RTS)** because it is heavily weighted to compensate for major head injury without multisystem injury or major physiologic changes.

The RTS is a physiologic scoring system that is also used to assess the severity of a trauma patient's injuries. Objective data used to calculate the RTS include the GCS score, systolic blood pressure, and respiratory rate. In addition to assessing injury severity, the RTS has also demonstrated reliability in predicting survival in patients with severe injuries. The highest RTS a patient can receive is 12; the lowest is 0. The RTS is calculated as shown in **TABLE 26-7**.

TABLE 26-7 Revised Trauma Score

Glasgow Coma Scale Score	Systolic Blood Pressure	Respiratory Rate	Value
13 to 15	>89 mm Hg	10 to 29 breaths/min	4
9 to 12	76 to 89 mm Hg	>29 breaths/min	3
6 to 8	50 to 75 mm Hg	6 to 9 breaths/min	2
4 to 5	1 to 49 mm Hg	1 to 5 breaths/min	1
3	0	0	0

© Jones & Bartlett Learning.

Street Smarts

Most EMS professionals will experience some type of traumatic incident while on duty. Approximately one-third of EMS professionals will be diagnosed with depression or posttraumatic stress disorder. The risk of suicide among EMS professionals is double that of non-public safety personnel. Take care of yourself. Know the resources that are available to you and seek help when needed.

YOU are the Provider SUMMARY**1. On the basis of the information provided, what are some possible injuries you may encounter?**

Rear-end impacts are known to cause whiplash-type injuries, particularly when the head and/or neck is not restrained by an appropriately placed headrest. In this type of crash, the cervical spine and surrounding area may be injured. The cervical spine is less tolerant of damage when it is bent backward. Other parts of the spine and the pelvis may also be at risk for injury. In addition, the patient may sustain a deceleration injury to the brain—that is, the third collision of the brain within the skull.

2. With the understanding that patients at this scene are most likely critical, how long should you remain on scene?

In most patients with multisystem trauma, definitive care requires surgical intervention; therefore, on-scene time should be limited to 10 minutes or less. This time frame is referred to as the platinum 10 minutes.

3. To which type of hospital should this patient be transported?

On the basis of the patient's MOI and obvious trauma, she should be transported to a Level I trauma center; however, many jurisdictions do not have readily available trauma centers. If a trauma center is not available, the patient should be transported to the closest appropriate facility, according to your protocols.

4. Does this patient meet the criteria for aeromedical evacuation?

This patient meets the criteria for aeromedical evacuation based on the suspected prolonged extrication

time and the amount of time that it would take to reach the trauma center.

The Association of Air Medical Services and MedEvac Foundation International recommendations serve as a guideline for local decision makers to develop more comprehensive protocols for the use of air medical transport. Always follow your local protocols when determining what type of patient transportation is appropriate.

5. What is the crackling sound heard on the neck, and how is it caused?

A fracture of the cartilage of the upper airway and larynx can result in the leakage of air into the soft tissue of the neck (subcutaneous emphysema), producing a crackling feeling when palpated. Either air in the circulation or an airway cartilage fracture may cause rapid death.

6. Now that the critical patient has departed the scene, what should you do with the deceased patient?

Appropriate procedures for handling a deceased patient depend on your local protocols. If your jurisdictional policies and procedures require you to transport the deceased to the funeral home or medical examiner, consult with on-scene law enforcement to ensure that you are clear to commence transport. If local custom does not allow for transport of the deceased, you should approach law enforcement and ascertain if there is any additional information they need from your service or if you are clear to depart the scene. In some cases, you will be asked to remain on scene with the body until the medical examiner arrives. Understand your local protocols and laws regarding the management of deceased persons.

Narrative

EMS dispatched to the 500 block of W 3rd Street for MVC. En route dispatch advises MVC is a result of high-speed police pursuit. Vehicle rear-ended another at approximately 85 to 90 miles per hour. Officers believe that patient in fleeing vehicle is deceased. On arrival triage performed. Driver in vehicle #2 tagged black based on unresponsiveness, cardiac arrest, and exposed brain matter (see PCR 20108752-1). Patient #2 found in small pickup with severe rear-end damage, unrestrained, severely entrapped with a GCS of 4 (E-1, V-2, M-1). Fire department on-scene for extrication. Helicopter requested. Once patient freed from wreckage, cervical collar applied, secured on long backboard. Patient found to have decreased respirations. Dual-lumen airway inserted without difficulty, ventilated at 12 breaths/min. Bilateral 18-gauge IVs established with 250-mL bolus of normal saline × 2 infused for hypotension. Physical exam reveals subcutaneous emphysema to base of neck. Abdomen noted to be distended and rigid. On arrival of flight crew, report given. Assisted with transfer of patient into helicopter. Care released to flight crew without further incident.

End of report

Prep Kit

Ready for Review

- MOI is the way in which traumatic injuries occur; it describes the forces (or energy transmission) acting on the body that cause injury.
 - Obtaining information about the MOI—that is, how the injuries occurred and what forces were likely involved—can be just as important as obtaining vital signs in assessing the patient. This information can help hospital staff to focus their attention on damage that may not be immediately obvious.
 - Significant mechanisms of injury include ejection from a vehicle; injury to more than one body system (multisystem trauma); falls from heights, motor vehicle and motorcycle crashes, vehicle versus pedestrian (or bicycle or motorcycle), gunshot wounds, and stabbings; unresponsiveness or altered mental status following trauma; and penetrating trauma to the head, chest, or abdomen.
 - Index of suspicion is an AEMT's awareness and concern for potentially serious underlying and unseen injuries. The index of suspicion should be partly based on the MOI.
 - Whether one or more body systems are involved, maintain a high index of suspicion for serious unseen injuries.
 - In every crash there are three collisions: the collision of the vehicle against another vehicle or some other object, the collision of the passenger against the interior of the car, and the collision of the passenger's internal organs against the solid structures of the body.
 - There are several types of collisions, including frontal crashes, rear-end crashes, lateral crashes, rollover crashes, and rotational crashes. Each type of collision will result in certain injury patterns and may cause blunt trauma, penetrating trauma, or both. Remember to determine whether the passenger was restrained, and note whether the airbag deployed.
 - In crashes involving a vehicle and a pedestrian, the pedestrian is likely to have unseen injuries.
- Estimate the speed of the vehicle that struck the patient. Determine whether the patient was ejected, what surface the patient landed on, and at what distance or whether the patient was struck and pulled under the vehicle. Evaluate the vehicle for structural damage that might indicate contact points with the patient.
- In a vehicle-versus-bicycle crash, evaluate the MOI as you normally would, but also evaluate damage to and the position of the bicycle. Assume spinal injury. If there is damage to the rider's helmet, suspect potential injury to the head.
 - When you are assessing the scene of a motorcycle crash, note any deformity of the motorcycle, the side with the most damage, the distance of skid in the road, the deformity of stationary objects or other vehicles, and the extent and location of deformity in the helmet.
 - The injury potential of a fall is related to the height from which the patient fell. The greater the height of the fall, the greater the potential for injury. Again, as in a motor vehicle crash, it is these internal injuries that are the least obvious on assessment but pose the gravest threat to life.
 - Penetrating trauma is classified as low energy, medium energy, or high energy. A projectile that impacts the body may fragment and cause cavitation—additional damage caused by the object moving inside the body and not along the suspected pathway.
 - You should suspect serious injuries in passengers who have been involved in a high-speed crash that results in massive damage to the vehicle. The same is true of a patient who has fallen from a substantial height, has sustained a high-velocity penetrating injury, or is the victim of an explosion or blast.
 - Multisystem trauma is a term that describes the injuries of a person who has been subjected to multiple traumatic injuries involving more than one body system such as head and spinal trauma, chest and abdominal

trauma, or chest and multiple extremity trauma. You must recognize multisystem trauma patients and provide rapid treatment and transportation.

- Limit on-scene time to the minimum amount necessary to correct life-threatening injuries and package the patient. On-scene time for critically injured patients should be less than 10 minutes.
 - The type of transport needed will vary based on the patient's condition. Options include standard EMS ground transport or critical care transport, which can occur over ground or air in a specialized ambulance or helicopter, respectively.
- As an AEMT, you will need to determine the most appropriate destination for trauma patients based on local protocols. There are four levels of trauma centers in the United States: Levels I, II, III, and IV. Extensive requirements apply to Level I facilities, which must be capable of providing every aspect of trauma care from prevention through rehabilitation. Level IV facilities are typically found in remote areas where no higher level of care is available.
 - Finally, it is important to be familiar with the American College of Surgeons Committee on Trauma decision scheme for field triage of injured patients.

Vital Vocabulary

arterial air embolism Air bubbles in the arterial blood vessels.

barometric energy The energy that results from sudden changes in pressure as may occur in a diving accident or sudden decompression in an airplane.

blast injuries Injuries resulting from explosions; possible injuries include internal injuries resulting from the pressure wave, penetrating trauma from shrapnel or from being thrown, blunt trauma from being thrown, and burns.

blunt trauma Result of force (or energy transmission) to impact on the body that causes injury without penetrating soft tissues or internal organs and cavities.

cavitation Formation of a temporary cavity that is produced by stretching of the tissue surrounding the point of impact—for example, when speed causes a bullet to generate pressure waves, which cause damage distant from the bullet's path.

chemical energy The energy released as a result of a chemical reaction.

coup-contrecoup Occurs when the brain continues its forward motion and strikes the inside of the skull, resulting in a compression injury to the anterior portion of the brain and stretching of the posterior portion.

deceleration The slowing of an object.

drag Resistance, such as air, that slows a projectile.

electrical energy Energy delivered in the form of high voltage.

entrance wound The point at which a penetrating object enters the body.

exit wound The point at which a penetrating object leaves the body, which may or may not be in a straight line from the entry wound.

flash burns Electrothermal injuries caused by arcing of electric current.

index of suspicion Awareness that unseen serious and/or life-threatening injuries may exist when determining the mechanism of injury.

kinetic energy The energy of a moving object.

kinetics The study of the relationship among speed, mass, vector direction, and physical injury.

mechanical energy The energy that results from motion (kinetic energy) or that is stored in an object (potential energy).

mechanism of injury (MOI) The forces, or energy transmission, applied to the body that cause injury; the way in which traumatic injuries occur.

multisystem trauma A term that describes the injuries of a person who has been subjected to multiple traumatic injuries involving more than

one body system; these patients have a high level of morbidity and mortality.

penetrating trauma Injury caused by objects that pierce and penetrate the surface of the body and injure the underlying tissues, such as knives and bullets, and damage internal organs and body cavities.

petechiae Small, purple, nonblanching spots on the skin.

potential energy The product of mass (weight), gravity, and height that is converted into kinetic energy and results in injury, such as from a fall.

pulmonary blast injuries Pulmonary trauma resulting from short-range exposure to the detonation of high-energy explosives.

Revised Trauma Score (RTS) A scoring system used for patients with head trauma.

thermal energy Energy transferred from sources that are hotter than the body, such as a flame, hot water, or steam.

trajectory The path a projectile takes after it is propelled from a weapon or explosion.

trauma lethal triad A combination of hypothermia, coagulopathy (poor blood clotting), and acidosis that is a major contributor to death in patients with severe traumatic bleeding.

trauma score A score that relates to the likelihood of patient survival of traumatic injuries with the exception of a severe head injury. It calculates a number from 1 to 16, with 16 being the best possible score taking into account the Glasgow Coma Scale score, respiratory rate, respiratory expansion, systolic blood pressure, and capillary refill.

tympanic membrane The eardrum; a thin, semi-transparent membrane in the middle ear that transmits sound vibrations to the internal ear by means of auditory ossicles.

work In the context of kinematics, the product of force times distance.

Chapter 27

Bleeding

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Bleeding

Pathophysiology, assessment, and management of

- Bleeding (pp 1279–1282, 1286–1291)
- Fluid resuscitation (Chapter 14, *Shock*)

Pathophysiology

Applies comprehensive knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

KNOWLEDGE OBJECTIVES

1. Discuss the physiology of perfusion. (pp 1276–1278)
2. Review the cardiac cycle, including the concepts of preload, afterload, and cardiac output. (pp 1278–1279)
3. Discuss the pathophysiology of external and internal bleeding. (pp 1279–1282)
4. Describe the characteristics of arterial bleeding, venous bleeding, and capillary bleeding. (pp 1279–1280)
5. Explain how to determine the nature of illness for internal bleeding, including identifying possible traumatic and nontraumatic causes. (p 1281)
6. List the signs and symptoms of internal bleeding. (p 1281)
7. List the signs and symptoms of hypovolemic shock. (pp 1281–1282)
8. Discuss the body's physiologic response to hemorrhaging. (pp 1282–1286)
9. Describe the four classes of hemorrhaging. (p 1285)
10. Describe the assessment process for patients with external and internal bleeding. (p 1286)
11. Discuss the importance of addressing life-threatening hemorrhage prior to airway and breathing concerns. (p 1287)
12. Describe what could be happening in the body when a patient with suspected internal bleeding becomes calm and still. (p 1288)
13. Discuss transport considerations for patients who are hemorrhaging. (pp 1287–1288)
14. Explain the emergency medical care of a patient with external bleeding. (pp 1292–1295)
15. Discuss situations in which a tourniquet may be used to control external bleeding. (pp 1295–1299)
16. List precautions to follow when applying a tourniquet. (p 1299)
17. Discuss the use of splints to control external bleeding. (p 1299)
18. Describe how hemostatic agents work to control severe hemorrhage. (pp 1293–1295)

19. List specific instances in which using a pneumatic antishock garment (PASG) to control bleeding may be an effective alternative. (p 1300)
20. Discuss assessment and management of bleeding from the nose, ears, and mouth. (p 1301)
21. Explain the emergency medical care of a patient with internal bleeding. (pp 1302–1303)
22. Explain how to manage hemorrhagic shock. (p 1304)

SKILLS OBJECTIVES

1. Demonstrate emergency medical care of the patient with external bleeding using direct pressure. (p 1293, Skill Drill 27-1)
2. Demonstrate emergency medical care of the patient with external bleeding using wound packing. (p 1295, Skill Drill 27-2)
3. Demonstrate emergency medical care of the patient with external bleeding using a commercial tourniquet. (pp 1297–1298, Skill Drill 27-3)
4. Demonstrate emergency medical care of the patient who shows signs and symptoms of internal bleeding. (p 1303, Skill Drill 27-4)

Introduction

The most current shift in trauma care takes the initial immediate focus off the airway and transfers it to circulation when there is evidence of severe external hemorrhage. Bleeding can be one of the most time-sensitive conditions you will face as an advanced emergency medical technician (AEMT).

The end goal in trauma care is to maintain perfusion. A patient with massive external hemorrhage must have the bleeding controlled immediately or exsanguination and death will result. In such a case, circulation takes temporary priority over airway and breathing. Addressing the airway instead of prioritizing bleeding control for severe external hemorrhage will result in ventilation and oxygenation to the lungs, but there would be inadequate blood remaining in the circulation to transport that oxygen to the tissues for perfusion, and that is a problem that cannot be corrected in the prehospital setting. A perfectly managed airway is inconsequential if the circulatory system is not able to deliver oxygen to the organs and remove accumulated waste products from them.

Bleeding can be external and obvious or internal and hidden. Either way, it is potentially dangerous, first causing weakness and, if left uncontrolled, eventually shock and death. The most common cause of shock after trauma is bleeding. This chapter begins with control of external hemorrhaging, covers recognition and management of internal hemorrhaging, and ends with transportation of patients with bleeding. Refer to Chapter 14, *Shock*, for guidelines on shock and fluid resuscitation.

Physiology and Perfusion

Recall that **perfusion** is the circulation of blood within an organ or tissue in adequate amounts to meet the cells' current needs for oxygen, nutrients, and waste removal. Blood enters an organ or tissue first through the arteries, then the arterioles, and finally the capillary beds (**FIGURE 27-1**). While passing through the capillaries, the blood delivers nutrients and oxygen to the surrounding cells and picks up the wastes they have generated. Then the blood leaves the capillary beds through the venules and finally reaches the veins, which take the blood back to the heart. Oxygen and carbon dioxide exchange takes place in the lungs. The anatomy and physiology of the cardiovascular system is covered in Chapter 7, *The Human Body*.

Blood must pass through the cardiovascular system at a speed that is fast enough to maintain adequate circulation throughout the body and slow enough to allow each cell time to exchange oxygen and nutrients for carbon dioxide and other waste products. Although some tissues, such as the lungs and kidneys, never rest and require a constant blood supply, most tissues require circulating blood only intermittently, especially when active. Muscles are a good example. When you sleep, they are at rest and require a minimal blood supply. However, during exercise, they need a very large blood supply. The gastrointestinal (GI) tract requires a high flow of blood after a meal. After digestion is completed, however, the GI tract functions well with only a fraction of that blood flow.

The autonomic nervous system monitors the body's needs from moment to moment and adjusts the blood flow as required. During emergencies,

FIGURE 27-1 Perfusion occurs when blood circulates through tissues or an organ to provide the necessary oxygen and nutrients and remove waste products.

© Jones & Bartlett Learning.

the autonomic nervous system automatically redirects blood away from other organs to the heart, brain, lungs, and kidneys. Thus, the cardiovascular system is dynamic, constantly adapting to changing conditions. At times, the system fails to provide sufficient circulation for every body part to perform its function. This condition is called hypoperfusion, or **shock**, which can result in death.

Safety

When you are caring for a patient who is bleeding, be sure to take necessary precautions to protect yourself from splashing or splattering. Wear appropriate protective equipment, including gloves, gown, mask, and eye protection. This equipment is especially important when arterial bleeding is present. Also remember that frequent, thorough handwashing between patients and after every run is a simple yet important protective measure.

Knowing which organs need adequate perfusion is the foundation on which your treatment of patients is based. Emergency medical care is designed to support the following systems:

- The heart (cardiovascular system)
- The brain and spinal cord (central nervous system)
- The lungs (respiratory system)
- The kidneys (renal system)

The heart requires constant perfusion or it will not function properly. The brain and spinal cord

YOU are the Provider

Part 1

It is opening day of deer season, and you and your partner are dispatched to a location in the backwoods for a man who has been shot. En route to the scene, dispatch advises you that this is an accidental shooting; the patient was climbing his tree stand, slipped, and fell, causing his rifle to discharge into his left bicep. Approximately 5 minutes from the scene, dispatch advises that law enforcement is on scene requesting you to expedite because the patient is bleeding badly.

On arrival, you meet the deputy who tells you that the patient is approximately one-third to one-half mile back on a trail, and he does not look good. As your partner grabs the jump kit and a tourniquet, you radio dispatch and request a helicopter to meet you at the scene. You find the patient propped against a tree, seated in a large puddle of blood. He is holding direct pressure to the wound; however, it still appears to be bleeding.

1. What are some possible hazards in this scene?
2. Is aeromedical evacuation appropriate with this patient?

cannot be without perfusion for more than 4 to 6 minutes or the nerve cells will be permanently damaged. Remember that cells of the central nervous system do not have the capacity to regenerate. The kidneys will be permanently damaged after 45 minutes of inadequate perfusion. Skeletal muscles cannot tolerate more than 2 to 3 hours of inadequate perfusion. The GI tract can exist with limited (but not absent) perfusion for several hours. These perfusion times are based on a normal body temperature (98.6°F [37.0°C]). An organ or tissue that is considerably colder is much better able to resist damage from hypoperfusion because of a slower metabolism. As a person's metabolism decreases, so does the need for oxygen and nutrients. This also decreases the production of waste products, which can be damaging if they are not promptly removed.

Words of Wisdom

When you are treating more than one patient, it is essential to change gloves every time you alternate between patients to prevent cross-contamination.

The Cardiac Cycle

The cardiac cycle is the repetitive pumping process that begins with the onset of cardiac muscle contraction and ends with the beginning of the next contraction. Myocardial contraction results in pressure changes within the cardiac chambers, causing the blood to move from areas of high pressure to areas of low pressure.

Preload is the amount of blood returned to the heart to be pumped out. It directly affects **afterload**, the pressure in the aorta or the peripheral vascular resistance (PVR), against which the left ventricle must pump blood. The greater the afterload, the harder it is for the ventricle to eject blood into the aorta. A higher afterload, therefore, reduces the stroke volume (SV), or the amount of blood ejected per contraction. To a large degree, afterload is governed by arterial blood pressure.

The cardiac cycle is connected to bleeding and shock through its relationship to blood pressure, the level of which is considered the dividing line between the stages of shock. In general terms, blood pressure is represented by the following equation:

$$\text{Blood pressure} = \text{Cardiac output (CO)} \times \text{Peripheral vascular resistance (PVR)}$$

where PVR is essentially the resistance in the vessels caused by vasoconstriction or vasodilation. Mean arterial pressure (MAP) is a measurement of arterial pressure in the vessels that perfuse the organs and indicates changes between CO and PVR. It can be estimated using the following equation:

$$\text{MAP} = \text{Diastolic pressure} + \frac{1}{3} \text{ Pulse pressure}$$

The **pulse pressure** is calculated by subtracting the diastolic blood pressure (DBP) from the systolic blood pressure (SBP):

$$\text{MAP} = \text{DBP} + \frac{1}{3} (\text{SBP} - \text{DBP})$$

Cardiac output (CO) is the amount of blood pumped through the circulatory system in 1 minute. CO is expressed in liters per minute (L/min). CO equals the SV multiplied by the pulse rate:

$$\text{CO} = \text{SV} \times \text{Pulse rate}$$

Factors that influence the SV, the pulse rate, or both will affect CO and, therefore, oxygen delivery (perfusion) to the tissues.

Increased venous return to the heart stretches the ventricles somewhat, resulting in increased cardiac contractility. This relationship, which was first described by the British physiologist Ernest Henry Starling, is known as the Frank-Starling mechanism or Starling law of the heart. Starling noted that if a muscle is stretched slightly before it is stimulated to contract, it will contract with greater force. Thus, if the heart is stretched, the muscle contracts more forcefully.

Although the amount of blood returning to the right atrium varies somewhat from minute to minute, a normal heart continues to pump the same percentage of blood returned, a measure called the ejection fraction. If more blood returns to the heart, the stretched heart pumps harder rather than allowing the blood to back up into the veins. As a result, more blood is pumped with each contraction, yet the ejection fraction remains unchanged: The amount of blood that is pumped increases, but so does the amount of blood returned. This relationship maintains normal cardiac function when a person changes positions, coughs, breathes, or moves.

The delivery of oxygen to the tissues is dependent on an adequate heart rate, SV, hemoglobin levels, and arterial oxygen saturation. If any of these elements is not adequate, tissues will become ischemic.

Words of Wisdom

Hematocrit blood testing measures the portion of red blood cells in whole blood. Normal hematocrit values vary, but in general are as follows:

- Men (any age): 40.7% to 50.3%
- Women (any age): 36.1% to 44.3%

If a patient's hematocrit level is out of range, the patient may have some sort of disease. Many different diseases or conditions could cause an abnormal level, resulting in anemia.

Pathophysiology

The pathophysiology of shock is covered in Chapter 14, *Shock*, but is relevant to the topic of bleeding. Review Chapter 14 for a discussion of the progression of shock and its signs and symptoms.

A **hemorrhage** is a discharge of blood from the blood vessels; it also simply means bleeding. Bleeding can range from a nicked capillary while shaving, to a severely spurting artery from a deep slash with a knife, to a ruptured spleen from being crushed against the steering column during a car crash. External bleeding (visible hemorrhaging) can often be controlled by using direct, even pressure, pressure dressings and/or splints, hemostatic dressings, tourniquets, or a pressure bandage (**FIGURE 27-2**). Internal bleeding (hemorrhaging that is not visible) is usually not controlled in the prehospital setting. Because internal bleeding is not as obvious, you must rely on signs and symptoms to determine the extent and severity of the hemorrhaging.

External Hemorrhaging

External bleeding is usually a result of a break in the skin. Its extent or severity is often a function of the type of wound and the types of blood vessels that have been injured. Typically, bleeding from an open artery is bright red (high in oxygen) and spurts in time with the pulse. The pressure that causes the blood to spurt also makes this type of bleeding

FIGURE 27-2 Most external bleeding can be controlled with direct pressure.

Courtesy of Rhonda Hunt.

difficult to control. As the amount of blood circulating in the body decreases, so does the patient's blood pressure and, eventually, the arterial spurting.

Blood from an open vein is much darker (low in oxygen) and flows steadily. Because it is under less pressure, most venous blood does not spurt and is easier to manage; however, it can still be life threatening. Bleeding from damaged capillary vessels is dark red and oozes from a wound steadily but slowly. Venous and capillary bleeding is more likely to clot spontaneously than arterial blood (**FIGURE 27-3**).

Words of Wisdom

Although hemorrhage is a common cause of hypovolemic shock, not all instances involve bleeding. Any loss of fluid, such as vomiting, diarrhea, or burns, can also lead to hypoperfusion.

These descriptions are not infallible. For example, considerable oozing from capillaries is possible when a patient has a large abrasion (such as in the case of road rash when a cyclist slides along the pavement without protective clothing). Similarly, varicose veins on the leg can produce copious bleeding.

Arteries may spurt initially, but as the patient's blood pressure decreases, often the blood simply flows. If an artery is incised directly across, or

**A****B****C**

FIGURE 27-3 **A.** Bleeding from capillary vessels is dark red and oozes from the wound slowly but steadily. **B.** Venous bleeding is darker red and flows steadily. **C.** Arterial bleeding is characteristically bright red and spurts in pulses.

© Jones & Bartlett Learning.

transversely, contractions of the smooth muscle in the arterial wall will often slow or tamponade bleeding. By contrast, if the artery is cut on a bias (such as a longitudinal incision), muscular contractions may pull the wound open farther, causing continual bleeding.

Some injuries that you might expect to be accompanied by considerable external bleeding do not always have serious hemorrhaging. For example, a person who falls off the platform at the train station and is run over by a train may have an amputation of one or more extremities, yet experience little bleeding because the wound was functionally cauterized by the heat of the train's wheels on the rail. Another example is a person who pulled over on the shoulder of the road and was removing the jack from his car's trunk when another motorist slammed into the rear

of the car, pinning him between the two vehicles. Most likely the person's legs are severely crushed but there may be little bleeding because the legs are compressed between the vehicles.

Words of Wisdom

Red blood cells are approximately one-third hemoglobin, the protein that gives them their red color. Hemoglobin is responsible for the cells' ability to transport oxygen and carbon dioxide. When hemoglobin binds with oxygen, oxyhemoglobin is formed. Oxyhemoglobin is bright red. When oxygen is released, deoxyhemoglobin is formed. Deoxyhemoglobin is darker red, and blood rich in deoxyhemoglobin may appear blue when seen through blood vessels.

Internal Hemorrhaging

Internal bleeding as a result of trauma may appear in any portion of the body. A fracture in areas where the soft-tissue compartment is small, such as the ankle, produces a somewhat controlled environment in which a relatively small amount of bleeding can occur. By contrast, bleeding into the trunk (that is, thorax, abdomen, or pelvis), because of its much larger space, tends to be severe and uncontrolled. Nontraumatic internal hemorrhage often occurs in cases of GI bleeding from the upper or lower GI tract, ruptured ectopic pregnancies, ruptured aneurysms, or other conditions.

You must always be alert to the possibility of internal bleeding and assess the patient for related signs and symptoms, particularly if the mechanism of injury (MOI) is severe.

Words of Wisdom

Consider any patient exhibiting signs and symptoms of shock without obvious external injury to have probable internal bleeding, usually in the abdominal cavity.

MOI for Internal Bleeding

A high-energy MOI should increase your index of suspicion for the possibility of serious unseen injuries such as internal bleeding in the abdominal

cavity. Internal bleeding is possible whenever the MOI suggests that severe forces affected the body. These forces include blunt and penetrating trauma. Internal bleeding commonly occurs as a result of falls, blast injuries, and automobile or motorcycle crashes. Remember that internal bleeding can result from penetrating trauma as well.

As you assess a patient, look for signs of injury using DCAP-BTLS (Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, and Swelling) over the chest or abdomen, including contusions, abrasions, lacerations, and other signs of injury or deformity. You should always suspect internal bleeding in a patient who has penetrating injury or blunt trauma.

Nature of Illness for Internal Bleeding

Internal bleeding is not always caused by trauma. Many illnesses can cause internal bleeding. Some of the more common causes of nontraumatic internal bleeding include bleeding ulcers, bleeding from the colon, ruptured ectopic pregnancy, and aneurysms.

Abdominal tenderness, guarding, rigidity, pain, and distention are frequent in these situations but are not always present. In older patients, dizziness, faintness, or weakness may be the first sign of nontraumatic internal bleeding. Ulcers or other GI problems may cause vomiting of blood, or bloody diarrhea or urine.

It is not as important for you to know the specific organ involved as it is to recognize that the patient is in shock and respond appropriately.

Signs and Symptoms of Internal Bleeding

The most common symptom of internal bleeding is pain. Substantial internal bleeding will generally cause swelling in the area of bleeding. Intra-abdominal bleeding will often cause pain and distention. Bruising is a sign of internal bleeding. It is most common in head, extremity, and pelvic injuries and can be a sign of substantial abdominal trauma. Bleeding into the chest may cause dyspnea in addition to tachycardia and hypotension. A bruise is also called a **contusion**, or **ecchymosis**. A **hematoma**, a mass of blood in the soft tissues beneath the skin, indicates bleeding into soft tissues

and may be the result of a minor or a severe injury. Bruising or ecchymosis may not be present initially, and the only sign of severe pelvic or abdominal trauma may be redness due to impact injury, skin abrasions, or pain.

Bleeding, however slight, from any body opening is serious. It usually indicates internal bleeding that is not easy to see or control. Bright red bleeding from the mouth or rectum or blood in the urine (**hematuria**) may suggest serious internal injury or disease. Nonmenstrual vaginal bleeding is always important.

Other signs and symptoms of internal bleeding in both trauma and medical patients include the following:

- **Hematemesis.** This is vomited blood. It may be bright red or dark red, or, if the blood has been partially digested, it may look like coffee-grounds emesis (a sign of upper GI bleeding, this is vomited blood that looks like used coffee grounds).
- **Hemoptysis.** This is bright red blood that is coughed up from the lungs by the patient.
- **Melena.** This is a black, foul-smelling, tarry stool that contains digested blood; it indicates lower GI bleeding.
- **Hematochezia,** the passage of bloody stools. If they contain bright red blood, this may indicate bleeding near the external opening of the colon or brisk lower GI bleeding. Hemorrhoids in the lower colon tend to cause hematochezia.
- **Pain, tenderness, bruising, guarding, or swelling.** These signs and symptoms may mean that a closed fracture is bleeding.
- **Broken ribs, bruises over the lower part of the chest, or a rigid, distended abdomen.** These signs and symptoms may indicate a lacerated spleen or liver. Patients with an injury to either organ may have referred pain in the right shoulder (liver) or left shoulder (spleen). You should suspect internal abdominal bleeding in a patient with referred pain.

The first sign of **hypovolemic shock** (hypoperfusion) is generally a change in mental status, such as anxiety, restlessness, or combativeness. In nontrauma patients, weakness, faintness, or dizziness on standing is another early sign. Changes in skin color or pallor (pale skin) are seen often in both

trauma and medical patients. Signs of hypoperfusion suggesting internal bleeding include the following:

- Altered level of consciousness
- Tachycardia
- Weakness, fainting, or dizziness at rest
- Thirst
- Nausea and vomiting
- Cold, moist (clammy) skin
- Shallow, rapid breathing
- Dull eyes
- Slightly dilated pupils that are slow to respond to light
- Capillary refill of more than 2 seconds in infants and children
- Weak, rapid (thready) pulse
- Decreasing blood pressure (very late sign)

Patients with these signs and symptoms are at risk. Some may be in danger. Even if their bleeding stops, it could begin again at any moment. Therefore, prompt transport is necessary.

Note that blood pressure is not a reliable indicator of early shock. The body generally compensates initially, keeping blood pressure within a normal range, and sometimes the compensation causes it to rise slightly. Medications may also mask changes in vital signs. To maintain central perfusion, blood will be shunted away from the periphery and the patient will present with pale, cool, mottled skin and decreased or absent radial pulses with an increased capillary refill time.

The Importance of Bleeding

For a typical adult weighing 176 pounds (80 kg), the total blood volume is approximately 10 pints (5 L). The body will not tolerate an acute blood loss of greater than 20% of this blood volume.^{1,2} If the typical adult loses more than approximately 2 pints (1 L) of blood, substantial changes in vital signs occur, including increasing heart and respiratory rates and decreasing blood pressure. An isolated femur fracture can easily result in the loss of 2 pints (1 L) or more of blood in the soft tissues of the thigh.

Because infants and children have less blood volume than adults, the same effect is seen with smaller amounts of blood loss. For example, a 1-year-old child has a total blood volume of approximately 2 pints (approximately 950 mL), so substantial symptoms of blood loss will occur after

only 3 to 6 ounces (100 to 200 mL) of blood loss. To put this in perspective, remember that a soft drink can contain about 11 ounces (345 mL) of liquid.

How well people compensate for blood loss is related to how rapidly they bleed. A healthy adult can comfortably donate 1 unit (1 pint [approximately 500 mL]) of blood during 15 to 20 minutes and most can adapt well to this decrease in blood volume. However, if a similar blood loss occurs in a much shorter period, **hemorrhagic shock** may rapidly develop, a condition in which low blood volume results in inadequate perfusion and even death. The body cannot compensate for such a rapid blood loss.

You should consider bleeding to be serious if the following conditions are present:

- A significant MOI, especially when the MOI suggests that severe forces affected the abdomen, chest, or both
- Poor general appearance of the patient
- Signs and symptoms of shock (hypoperfusion)
- Substantial amount of blood loss
- Rapid blood loss
- Uncontrollable bleeding

In any situation, severe blood loss is a serious problem and should be addressed prior to other assessments or interventions. Minor blood loss can be managed once you have assessed and treated airway, breathing, and circulation.

Physiologic Response to Hemorrhaging

Injuries and some illnesses can disrupt blood vessels and cause bleeding. On its own, bleeding tends to stop rather quickly, within approximately 10 minutes, in response to internal clotting mechanisms and exposure to air. When vessels are lacerated, blood flows rapidly from the open vessel. In response, the open ends of the vessel begin to narrow, or vasoconstrict. This reduces the amount of bleeding. Platelets aggregate at the site, plugging the hole and sealing the injured portions of the vessel. This process is called **hemostasis**. Bleeding will not stop if a clot does not form, unless the injured vessel is completely cut off from the main blood supply. Direct contact with body tissues and fluids or the external environment commonly triggers the blood's clotting factors.

Words of Wisdom

Motivated by many tragedies throughout the country, in October 2015, the White House launched the *Stop the Bleed* campaign in an attempt to train, equip, and empower bystanders to act in an emergency situation prior to the arrival of professional help³ (FIGURE 27-4). The idea is that by providing bystanders and emergency responders such as law enforcement with the skills and basic tools needed to stop uncontrolled bleeding, many lives could be saved. The principles include three key actions, as shown in the figure.

This initiative applies in not only terror attacks, but also natural disasters.

Many agencies, including the National Security Council at the White House, American Heart Association, American Red Cross, American College of Surgeons, Hartford Consensus, National Association

of Emergency Medical Technicians, Charlotte Douglas International Airport, Johnson & Johnson, and the Harvard Kennedy School collaborated for over a year to develop this campaign.⁴ The goal is to make the *Stop the Bleed* logo as recognizable as *stop, drop, and roll* and to put the materials in the hands of the public sector. To get these materials into the public, some venues have placed kits in the same location as automated external defibrillators (AEDs). Items included in the kits range from nitrile gloves for personal protection to tourniquets, compression dressings, rolled gauze, and trauma shears.

The key to the success of this initiative is widespread education of the public and having kits available for use. Emergency medical services (EMS) providers can provide a vital link in this accomplishment.

FIGURE 27-4 Three actions you can take to help save a life.

Despite the efficiency of this system, it may fail in certain situations. Many medications, including anticoagulants such as aspirin and prescription blood thinners, interfere with normal clotting. Beta-blockers can also prevent vasoconstriction, resulting in excessive bleeding. With a severe injury, the damage to the vessel may be so large that a clot cannot completely block the hole. Sometimes, only part of the vessel wall is cut, preventing it from constricting. In these cases, bleeding will continue unless it is stopped by external means. Occasionally, blood loss occurs rapidly. In these cases of acute blood loss, the patient might die before the body's hemostatic defenses of vasoconstriction and clotting can help. **TABLE 27-1** shows the classes of hemorrhaging.

A small portion of the population lacks one or more of the blood's clotting factors. This condition is called **hemophilia**. There are several forms of hemophilia, most of which are hereditary and some of which are severe. Sometimes, bleeding may occur spontaneously in a person with hemophilia. Because the patient's blood does not clot, all injuries, no matter how trivial, are potentially serious. A patient with hemophilia should be transported immediately. Bleeding disorders are

Words of Wisdom

The American College of Surgeons, in collaboration with the medical community, representatives from governmental and nongovernmental agencies, and various emergency medical response organizations, among others, developed a national protocol to maximize survivability from active shooter and other mass-casualty incidents. These recommendations, called the Hartford Consensus, emphasize a continuum of care from initial response to definitive care that involves the seamless integration of hemorrhage control intervention.⁵

An integrated active shooter response should include the critical actions contained in the acronym **THREAT**:

- **T**hreat suppression
- **H**emorrhage control
- **R**apid **E**xtrication to safety
- **A**ssessment by medical providers
- **T**ransport to definitive care

Life-threatening bleeding from extremity wounds is best controlled initially through use of tourniquets, whereas internal bleeding resulting from penetrating wounds to the chest and trunk is best addressed through immediate transport to a medical facility.

YOU are the Provider

Part 2

The patient states that about 15 minutes ago, he was up approximately 14 feet above the ground in the tree stand, when he slipped and fell. When he landed, his rifle discharged into his left bicep. He is reporting pain to his obviously deformed right lower extremity, pain to his left bicep, and dizziness. As your partner attempts to obtain vital signs, you examine the wound and find a small entrance wound and a gaping wound on the posterior bicep. You determine the bleeding is arterial. You immediately apply a tourniquet. The patient denies having any other injury, stating it is only his leg and arm that hurt. You also request the local search-and-rescue team to be dispatched to your location to assist in extricating the patient to a safe landing zone.

Recording Time: 1 Minute

Appearance	Anxious
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent
Breathing	Rapid, panting
Circulation	Weak, thready radial pulses; skin is pale

3. Does this patient require spinal immobilization?
4. How would you transport this patient one-half mile to the parking area where the helicopter could land?

TABLE 27-1 Estimated Fluid and Blood Loss for a 154-lb (70-kg) Patient

	Class I	Class II	Class III	Class IV
Blood loss (mL)	<750	750–1,500	1,500–2,000	>2,000
% Blood loss	<15	15–30	30–40	>40
Heart rate (beats/min)	Minimally elevated or normal	100–120	≥120, thready	Marked tachycardia
Systolic blood pressure	Within normal limits	Minimal or no change	Substantial decrease	Substantial depression
Pulse pressure	Within normal limits	Narrow	Narrow	Very narrow
Capillary refill	Within normal limits	May be delayed	Delayed	Delayed
Respiratory rate (breaths/min)	14–20	20–24	Markedly elevated	Markedly elevated
Central nervous system/mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic
Skin condition	Cool, pink	Cool, moist	Cold, pale, moist	Cold, pale
Urine output (mL/h)	>30	20–30	Diminished	Minimal or none
Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

© Jones & Bartlett Learning.

Words of Wisdom

Hemostasis is difficult in areas where movement is involved, such as over a joint. Movement disrupts clotting, increasing hemorrhaging. Removal of a bandage may also disrupt clotting, causing bleeding to continue.

discussed in Chapter 21, *Endocrine and Hematologic Emergencies*.

Trauma Triad of Death

The trauma triad of death is a combination of hypothermia, coagulopathy, and acidosis that substantially increases mortality in trauma patients. These three conditions feed on one another in a positive feedback loop, rapidly worsening the patient's condition.

Even mild hypothermia can begin to inhibit the chemical reactions involved in the clotting process. **Coagulopathy**, the disruption of the body's ability to clot, can result in further hemorrhage, leading to increasing hypoperfusion. This hypoperfusion causes the cells to use anaerobic metabolism, releasing additional acidic compounds into the blood. This acidosis reduces myocardial performance, further reducing oxygen delivery and body metabolism, resulting in increased hypothermia. If this loop continues uninterrupted, the rapidly worsening shock will result in death of the trauma patient. Thus, you must seek to identify the conditions of hypothermia, coagulopathy, and acidosis in the setting of trauma and intervene where possible.

Hypothermia is often easy to identify if looked for and can be the easiest condition to treat. Trauma patients must be kept warm. This is especially true if the patient is also subjected to environmental hypothermia, such as a motor vehicle crash in cold weather. However, you must keep in mind that

hypothermia in the trauma triad of death refers to the body's inability to maintain normal operating temperature. This sign may be subtle and easy to overlook.

Patient Assessment

Scene Size-up

The assessment of any patient begins with a thorough scene size-up and proceeds to your general impression and primary survey. After the scene is considered safe, you will need to take the appropriate standard precautions. Depending on the severity of bleeding and your general impression, these precautions will entail gloves, mask, eye shield, and, when the patient is bloody or blood is spurting, a gown (**FIGURE 27-5**).

When patients have serious external blood loss, it is often difficult to determine visually the amount of blood lost. Blood will look different on different surfaces, such as when it is absorbed in clothing or when it has been diluted when mixed in water. Attempt to determine the amount of external blood loss, but remember that this is not crucial and the presentation and assessment of the patient must direct patient care and treatment.

Determine the nature of the illness (NOI) (such as bloody emesis or bloody stool), or the MOI (such as an overturned chair). Consider the need for additional resources, such as an advanced life support unit. Be sure to also consider environmental factors in your decision making. For example, caring for a sick or injured victim of a car crash on a clear, sunny day is a bit different than treating the same victim during a snowstorm. Extreme hot or cold weather can worsen a patient's overall condition.

FIGURE 27-5 Depending on the severity of bleeding and your general impression, standard precautions will entail gloves, mask, eye shield, and, in some cases, a gown.

YOU are the Provider

Part 3

After securing the tourniquet around the upper arm, you note a complete cessation of blood flow from the wound. Having taken care of the immediate life threat, you contact dispatch to obtain the estimated time of arrival of the helicopter, which is approximately 16 minutes.

Recording Time: 4 Minutes

Respirations	32 breaths/min, rapid
Pulse	Weak and thready, 139 beats/min
Skin	Diaphoretic, cool, pale, and clammy
Blood pressure	74 mm Hg by palpation
Oxygen saturation (SpO₂)	Not obtained
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- What class of hemorrhaging is occurring in this patient?
- What are the indications for a tourniquet, and when do you remove it?

Primary Survey

Bleeding that you can control (such as external bleeding that responds to a pressure bandage) and bleeding that you cannot control (such as a bleeding peptic ulcer) are serious emergencies. Substantial bleeding, internal or external, is an immediate life threat. Consequently, the primary survey of the patient includes a search for life-threatening bleeding. As you approach a trauma patient, you must note important indicators that may alert you to the seriousness of the patient's condition. For example, patients with external bleeding may have blood stains on their clothing. Be aware of obvious signs of injury and distress, such as facial grimace.

Perform a rapid full-body scan of the patient. If found, life-threatening hemorrhage must be controlled *first*, even before airway and breathing. Therefore, follow the XABCDE mnemonic for trauma, assessing for and managing exsanguinating hemorrhage first. If the hemorrhaging cannot be controlled in the field, all your efforts should concentrate on attempting to control the bleeding as you rapidly transport the patient to the emergency department (ED). When life-threatening external bleeding is seen, you must also begin treatment of shock as quickly as possible. Treat for shock if needed by applying oxygen, placing the patient in the proper position, improving circulation with intravenous (IV) fluid as needed, and maintaining a normal body temperature.

However, if the patient has minor external bleeding, you can note it and move on with the primary survey; management of this problem can wait until the patient has been properly assessed and prioritized. Do not become sidetracked by applying dressings and bandages to a patient who has much more serious problems. Non-life-threatening bleeding, such as from abrasions, can be bandaged later in your assessment as necessary.

Determine the patient's level of consciousness using the AVPU scale (Awake and alert, responsive

to Verbal stimuli, responsive to Pain, Unresponsive). These indicators will help you determine whether the patient is sick or not sick; this assists you in developing an index of suspicion for serious illness or injuries related to internal bleeding. Internal bleeding includes bleeding into any cavity or space within the body and may be severe and life threatening. Without proper assessment, internal bleeding may go undetected.

After addressing life-threatening bleeding, next manage immediate threats to life involving the airway and breathing. Consider the need for manual spinal stabilization prior to airway management. Ensure that the patient has a patent airway. If you observe bleeding from the mouth or facial areas, keep the suction unit within reach.

You must be able to quickly assess pulse rate and quality; determine the skin condition, color, and temperature; and check the capillary refill time to help establish the potential for internal bleeding and shock. Pale or gray, cool, moist skin suggests a perfusion problem.

In some instances, patients may become quiet and calm because of excessive blood loss and shock state. As mentioned, estimating the amount of blood loss by the size of a pool of blood or the amount of blood on clothing may not be accurate, especially if the patient has moved. Assessing the patient for signs of shock is a better indicator of the amount of blood loss.

Any internal bleeding must be treated promptly. The signs of internal hemorrhaging (such as discoloration or hematoma) do not always develop quickly, so you must rely on other signs and symptoms and an evaluation of the MOI to make this diagnosis. Pay close attention to patient reports of pain or tenderness, development of tachycardia, and pallor. If you suspect internal bleeding, begin management by keeping the patient warm and administering supplemental oxygen using a nonrebreathing mask at 15 L/min.

Special Populations

In older patients, dizziness, syncope, or weakness may be the first sign of nontraumatic internal hemorrhaging.

Words of Wisdom

Do not delay transport to complete an assessment, particularly when substantial bleeding is present, even if the bleeding is controlled. The assessment can be started during transport.

When making a transport decision in cases of hemorrhaging, the issue is not whether the patient will be transported, but rather how fast the transport decision should be made and where the patient should be taken for definitive care. There are a few exceptions to this rule—for example, if you are standing by at a sporting event or concert and are asked by a “walk-in” to evaluate a minor wound that has been bleeding. The decision to transport a patient with even a relatively minor wound should take into consideration factors such as the need for stitches, whether the patient has had a tetanus shot in the past 10 years, and whether the patient or a companion is reliable and will follow up properly; finally, the decision may depend on local protocols.

Most patients with internal or external hemorrhaging will need to be transported to a hospital for further care. Consideration for the priority of the patient and the availability of a regional trauma center should be your concerns when making a transport decision. Patients who have severe internal or external bleeding, especially if uncontrolled, will often be candidates for surgery and should be transported immediately to an appropriate facility. Patients with specific causes of bleeding such as major trauma or specific devastating wounds, such as leg amputation or glove avulsion (also called degloving injury), should be taken to a facility that is fully prepared to care for the patient. Paramedic backup or rendezvous may be needed when the patient requires advanced procedures such as endotracheal intubation, vasopressor drugs, or cardiac monitoring. In EMS systems with air medical transport available, it may be appropriate to consider this method of transportation for a patient with suspected severe internal or uncontrollable external bleeding, depending on the distance to the appropriate facility and the degree to which use of the aeromedical service can expedite arrival of the patient at the facility.

History Taking

After the primary survey is complete, investigate the chief complaint and be alert for signs or symptoms of other injuries due to the MOI and/or NOI. Internal bleeding can be found in medical and trauma patients. If the bleeding is severe, you may have identified it in the primary survey and begun

treatment and rapid transport to the hospital. Carefully assess the MOI in trauma patients because it may be your best indicator that the patient has sustained an internal injury and may be bleeding. **TABLE 27-2** lists some MOIs that can give clues about internal bleeding. In addition to evaluating the MOI, be alert for the development of shock when you suspect internal bleeding. In a responsive trauma patient who has an isolated injury with a limited MOI, consider a detailed physical exam before assessing vital signs and obtaining a history.

When you encounter a patient who is bleeding, avoid focusing solely on the bleeding. With substantial trauma, assess the entire patient, looking for the source of the problem, any preexisting illnesses, and other issues.

Words of Wisdom

Common blood thinners include antiplatelets such as aspirin, clopidogrel (Plavix), and ticagrelor (Brilinta), and anticoagulants such as warfarin (Coumadin), rivaroxaban (Xarelto), dabigatran (Pradaxa), apixaban (Eliquis), and edoxaban (Savaysa). These are often prescribed for patients with a history of stroke, pulmonary embolism, deep vein thrombosis, or cardiovascular disease.

Gather information on the patient’s chief complaint using the OPQRST-I (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, Interventions prior to EMS arrival) mnemonic and obtain a SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history. Ask these patients if they experienced any dizziness or syncope. Are there any signs and symptoms of hypovolemic shock? Ask if they take any blood-thinning medications, because bleeding is generally more profuse and difficult to control in patients who take these; also, medications for the heart or blood pressure may interfere with the ability to vasoconstrict and compensate. Ask about any history of clotting insufficiency. Is there any pain, tenderness, bruising, guarding, deformity, distention, discoloration of the affected area, or swelling? These signs and symptoms may indicate internal bleeding.

TABLE 27-2 The Mechanism of Injury: Indicators of Internal Bleeding

Mechanism of Injury	Potential Internal Bleeding Sources
Fall from a ladder striking head	Head injury or hematoma
Fall from a ladder striking extremities	Possible fractures; consider chest injury
Fall on outstretched arm	Possible broken bone or joint injury
Unrestrained driver in head-on collision (up-and-over route)	Head and neck, chest, abdomen injuries
Unrestrained driver in head-on collision (down-and-under route)	Knee, femur, hip, and pelvis injuries
Unrestrained front-seat passenger, side-impact collision with intrusion into vehicle	Humerus fracture, injuring the chest wall (possible flail chest); pelvis and acetabulum injuries
Unrestrained driver crushed against steering column	Chest and abdomen injuries, ruptured spleen, neck trauma
Road bike or mountain bike (over the handlebars)	Fractured clavicle, road rash, head trauma if no helmet worn
Abrupt motorcycle stop, causing rider to catapult over the handlebars	Fractured femurs, head and neck injuries
Diving into the shallow end of a swimming pool	Head and neck injuries
Assault or fight	Punching or kicking injury to chest, abdomen, and face
Blast or explosion	Injury from direct strike with debris; indirect and pressure wave in enclosed space
Child struck by car	Fractured femoral shaft, intrathoracic or intra-abdominal injuries, contralateral head injury (Waddell triad)
Child thrown or falls from height	Usually a headfirst impact, causing head injury

© Jones & Bartlett Learning.

Special Populations

Remember that vital signs vary depending on age. What is normal for an adult patient will not be normal for a pediatric patient. Refer to Chapter 10, *Patient Assessment*, for vital signs by age group.

Words of Wisdom

Use pulse oximetry as a diagnostic tool to help determine the patient's oxygenation. However, remember that a patient showing signs of hypoperfusion will not have an accurate pulse oximetry reading. Treat the patient, not the diagnostic tool!

Secondary Assessment

As described earlier, the secondary assessment is a detailed, comprehensive examination of the patient to uncover injuries or illness that may have been missed during the primary survey. In some cases, such as those that involve a critically injured patient or a short transport time, there may not be time to conduct a secondary assessment.

When you are performing a secondary assessment, record vital signs, complete a focused assessment of pain, and attach appropriate monitoring devices. The examination should include a systematic full-body exam. The full-body exam assesses each body system as discussed in Chapter 10, *Patient Assessment*.

Assess the respiratory system. Specifically assess the airway for patency and determine the rate

and quality of respirations. In the neck, look for distended neck veins and a deviated trachea. Note, however, that these classic signs may not be present in the patient with hypovolemia. In the chest, check for paradoxical movement of the chest wall and bilateral breath sounds.

Assess the cardiovascular system, specifically the rate and quality of pulses.

Assess the neurologic system to formulate baseline data to guide further decisions. This examination should include level of consciousness, pupil size and reactivity, motor response, and sensory response.

Assess the musculoskeletal system. Perform a detailed full-body examination. Look for DCAP-BTLS to be sure you have quickly found all problems and injuries. Assess all anatomic regions. When you are examining the head, be alert for raccoon eyes, Battle sign, and/or drainage of blood or fluid from the ears or nose. In the abdomen, feel all four quadrants for tenderness or rigidity. In the extremities, record the pulse and motor and sensory function.

Obtain baseline vital signs to observe the changes that may occur during treatment. In an adult, a systolic blood pressure of less than 100 mm Hg with a weak, rapid pulse should suggest to you the presence of hypoperfusion in a patient who may have substantial bleeding. Because infants and

children have less blood volume than adults, the same effect is seen with smaller amounts of blood loss.

In geriatric patients, the pulse rate may not increase with early shock; therefore, if possible, try to determine the patient's normal baseline blood pressure and circulatory status.

In addition to hands-on assessment, use monitoring devices to quantify oxygenation and circulatory status. You may use a noninvasive technique to monitor blood pressure and a pulse oximeter to evaluate the effectiveness of oxygenation. Always assess the patient's blood pressure with a sphygmomanometer and stethoscope (manually) before using a noninvasive blood pressure monitor to establish a baseline blood pressure and to determine the accuracy of the noninvasive blood pressure machine. Also consider the use of end-tidal carbon dioxide monitoring for patients exhibiting signs of hypoperfusion that may alter pulse oximetry readings.

Reassessment

Patient reassessment is an important tool to see how your patient is doing over time. Reassess the patient, especially in the areas that showed abnormal findings during the primary survey. The signs and symptoms of internal bleeding are often slow

YOU are the Provider

Part 4

Noting the vital signs, recognizing the helicopter ETA, and recognizing the seriousness of the injury, you elect to start two 18-gauge IV lines and administer 250-mL boluses of normal saline, checking vital signs again after each bolus until a systolic blood pressure of 80 mm Hg has been achieved. Supplemental oxygen at 15 L/min is also applied. The patient requests something for pain. You inform him that paramedics are en route and they will be able to administer pain medication soon after arrival. Just then, you see the local search-and-rescue team arriving.

Recording Time: 12 Minutes

Respirations	34 breaths/min, rapid
Pulse	Weak and thready, 142 beats/min
Skin	Diaphoretic, cool, pale, and clammy
Blood pressure	76 mm Hg by palpation
Oxygen saturation (SpO₂)	97% on 100% oxygen
Pupils	PERRLA

7. Why should you administer 250-mL boluses until a systolic blood pressure of 80 mm Hg is achieved?

to present because of their covert nature. The reassessment is your best opportunity to determine whether your patient's condition is improving or getting worse. Assess the effectiveness of any interventions, especially tourniquets, and treatments provided to the patient.

Vital signs show how well your patient is doing internally. In all cases of severe bleeding, obtain the patient's vital signs every 5 minutes en route to the ED. Is the patient's airway still patent and breathing still adequate? Is the oxygen helping the patient to breathe easier? Is your treatment for shock resulting in better perfusion of the vital organs? Is the bandage controlling the bleeding?

In patients with severe external bleeding, it is important to recognize, estimate, and report the amount of blood loss that has occurred and how rapidly or during what period it occurred. This can be a challenge to estimate, especially if the surface the patient is on is wet or absorbs fluids or if the environment is dark. For example, you may report that approximately 1 pint (approximately 0.5 L) of blood was lost or that the bleeding soaked through three trauma dressings. Report this information to hospital personnel during transport to allow the hospital to evaluate needed resources, such as the availability of surgical suites, surgeons, and other specialty providers.

With internal bleeding, describe the MOI/NOI and the signs and symptoms that make you think internal bleeding is occurring.

Your transfer report at the hospital should update hospital personnel on how your patient has responded to your care. Be sure your paperwork reflects all of the patient's injuries and the care you have provided.

Assessment Pearls

- Maintain a high index of suspicion for occult injuries based on the MOI. Not every significant injury shows obvious signs and/or symptoms.
- Think shock! Learn to recognize the early signs of shock and provide aggressive treatment.
- When signs of shock are not present and there is a significant MOI, consider any medications the patient is taking that may be masking compensation.
- Never delay transport to complete an assessment or begin treatment that can be done en route, especially if there is significant bleeding or the potential for internal bleeding.
- When direct pressure is ineffective, consider a tourniquet or wound packing. Time is not on the bleeding patient's side.
- Always leave tourniquets in full view.
- Pulse oximetry is inaccurate in states of hypoperfusion. End-tidal carbon dioxide monitoring is the gold standard for these patients, especially when hemorrhage is combined with a head injury.

Special Populations

Older adult patients are more likely to take medications that interfere with normal compensatory mechanisms, such as beta-blockers, calcium channel blockers, and other antidysrhythmics. The kidneys also atrophy with age and, therefore, are less responsive to fluid conservation; the blood vessels may be affected by atherosclerosis and less able to shunt blood to vital areas. In addition, other medical conditions can be exacerbated during shock states; for instance, ischemia is more likely to interfere with CO in patients with a history of myocardial infarction or angina.

Pediatric patients have underdeveloped kidneys, resulting in an inability to conserve fluid unlike that of an adult. Consequently, they have a lower tolerance

for volume loss. In addition, children compensate by vasoconstriction better than adults do. This factor tends to allow them to maintain a compensatory state and good blood pressure for a longer period, until the point when their vital signs collapse abruptly, possibly followed by death. They will compensate well for blood loss and then crash quickly. An additional complication in small children is their relatively large surface area-to-weight ratio, which means they feel cold more easily, resulting in coagulation difficulties.

Pregnant patients normally will have a faster pulse, greater blood volume, lower blood pressure, and nausea. Treat these patients aggressively according to the MOI and treat for shock; do not automatically assume the altered signs are a result of the pregnancy.

Emergency Medical Care

External Hemorrhaging

Most external bleeding can be managed with direct pressure, combined with pressure dressings and/or splints, although arterial bleeding may take 5 or more minutes of direct pressure to form a clot. Military experience has proven that tourniquets can effectively and safely control hemorrhage without an increase in complications.⁶ For this reason, the use of a **tourniquet** is preferred for external bleeding in an extremity that cannot be controlled with direct pressure and a pressure dressing. If a tourniquet is deemed necessary, it should be applied quickly and not released until a physician is present.

Special Populations

In pregnant patients, shock leads to shunting of blood away from the fetus in an attempt to preserve the mother. The closer the maternal blood pressure is to normal, the better perfused the fetus is likely to be.

Always observe standard precautions. As with all patient care, ensure that the patient has an open airway and is breathing adequately. Whenever you suspect bleeding, either external or internal, provide high-flow oxygen and assist ventilation if needed with attention to cervical spine control in trauma patients as indicated. To control external bleeding, follows the steps in **SKILL DRILL 27-1**.

Most instances of external bleeding can be controlled simply by applying direct local pressure to the bleeding site, including the area just proximal and distal to the injury. This method is by far the most effective way to control external bleeding. Pressure stops the flow of blood and permits normal coagulation to occur. You may apply pressure with your gloved fingertip or hand, over the top of a sterile dressing if one is immediately available. If there is an object protruding from the wound, apply a bulky dressing to stabilize the object in place, and apply pressure as best you can without interruption until bleeding is controlled. Never remove an impaled object from a wound unless it is through the cheek and interferes with the airway, or in the chest and interferes with chest compressions.

Words of Wisdom

If an impaled object prevents transport of a patient because of its size or positioning, proper treatment includes attempting to cut through the object to create a manageable size while leaving it in place. If you determine that removal of the impaled object is mandatory in order to accomplish transport, contact medical control prior to removal of the object for direction as to how to proceed.

After you have applied a dressing and controlled the bleeding, you can create a pressure dressing to maintain the pressure by firmly wrapping a sterile, self-adhering roller bandage around the entire wound. Use 4 × 4-inch or 4 × 8-inch sterile gauze pads for small wounds and sterile universal dressings for larger wounds.

Cover the entire dressing, above and below the wound. Stretch the bandage tight enough to control bleeding. Check the distal pulse before and after applying the dressing; if you were able to palpate a distal pulse before applying the dressing, you should still be able to palpate a distal pulse on the injured extremity after applying the pressure dressing.

Bleeding will almost always stop when the pressure of the dressing exceeds arterial pressure. This will assist in controlling bleeding and helping blood to clot.

If direct pressure fails to immediately stop the hemorrhaging, apply a tourniquet to the groin or axilla above the site of the bleeding. If this is not possible because the bleeding is too far proximal, consider a junctional tourniquet or wound packing with a hemostatic dressing if available (always follow local protocols). Otherwise, apply direct pressure and hold it until you arrive at the hospital.

Some of the bleeding associated with broken bones occurs because the sharp ends of the bones lacerate vessels, muscles, and other tissues. As long as a fracture remains unstable, the bone ends will move and continue to cause damage to tissues and vessels. This may also include breaking up clots that have partially formed, resulting in ongoing bleeding. Therefore, stabilizing a fracture and decreasing movement is a high priority in the prompt control of bleeding. Often, simple splints will quickly control bleeding associated with a fracture.

Skill Drill 27-1 Managing External Hemorrhage

Step 1

Take standard precautions. Maintain the airway with cervical spine immobilization if the MOI suggests the possibility of spinal injury. Apply direct, even pressure over the wound with a dry, sterile dressing.

Step 2

If the bleeding stops, apply a pressure dressing and/or splint. Hold the pressure dressing in place using gauze.

Step 3

If direct pressure does not rapidly control bleeding on an extremity injury, apply a tourniquet to the axilla or groin region of the bleeding extremity.

Step 4

Tighten the tourniquet until the bleeding stops. Write "TK" and the exact time (hour and minute) that you applied the tourniquet on the patient's forehead. Position the patient supine unless contraindicated. Administer oxygen as necessary. Keep the patient warm, transport promptly, monitor the serial vital signs, and watch diligently for developing shock.

All images © Jones & Bartlett Learning.

(FIGURE 27-6). If the patient is unstable, however, do not waste time splinting a fracture.

After bleeding is controlled and a sterile dressing and pressure bandage have been applied, keep the patient warm and in the appropriate position. Allow the patient's condition to determine the mode of transport.

Wound Packing and Hemostatic Agents

Although it has become the standard of care to apply direct pressure initially, and then apply a tourniquet on wounds that continue to bleed, wound packing has been shown to further inhibit blood

FIGURE 27-6 Use of a simple splint will often quickly control bleeding associated with a fracture. As long as a fracture is not immobilized, the bone ends are free to move and may continue to injure partially clotted vessels.

Words of Wisdom

Hemostatic agents were primarily used in the military to promote hemostasis or, in other words, to stop profuse bleeding, but are rapidly gaining prevalence in the civilian world. These agents may consist of granules contained in a dressing. The agent absorbs the water component of blood, thereby concentrating the clotting factors, activating platelets, and enhancing the coagulation cascade.

loss and increase patient survival.⁷⁻⁹ The purpose of packing the wound is to create an *internal pressure dressing* that fills the wound cavity and applies pressure from within. Plain gauze may be used to pack open wounds, particularly those on the torso or in other areas where tourniquet placement is impossible and direct pressure is not adequate; hemostatic agents (discussed later) can also be used.

Wound packing involves taking standard initial steps to control the bleeding, including direct pressure, tourniquets, and other applicable tools and techniques. Simply push the gauze into the wound with an index finger to completely and tightly pack the wound cavity. The goal is to contact the source of the bleeding if possible and to fill the cavity. If extra gauze is left over, place it on top of the wound. Hold firm, direct manual pressure on the wound for at least 3 minutes or secure the wound with a snug pressure dressing over the wound.

FIGURE 27-7 Hemostatic agents are being used by some EMS systems to control severe hemorrhage, especially in areas of the body where a tourniquet cannot be placed.

© North American Rescue®, LLC. All rights reserved.

Wound packing works by absorbing liquid from the blood, helping to concentrate clotting factors; helping to transfer external direct pressure to deeper blood vessels that are the source of bleeding; and, if using hemostatic dressings (specialized dressings impregnated with various chemical compounds to enhance hemostasis), chemically accelerating the clotting process.¹⁰

The US military has been successfully using wound packing with standard gauze and hemostatic agents to control severe hemorrhage, especially in areas where a tourniquet cannot be placed (such as junctional wounds [inguinal and axilla]), for many years, and the techniques are now moving into civilian EMS.¹⁰ A **hemostatic agent** works by causing enhanced clot formation in the wound site: the agent adheres to the damaged tissue and either dehydrates the blood or undergoes a chemical reaction that stimulates the natural blood clotting cascade (ie, the intrinsic pathway) (**FIGURE 27-7**). Ideally, the bleeding should be stopped in 2 minutes or less.

Hemostatic dressings can be used together with wound packing and direct pressure when direct pressure alone is ineffective. These dressings have the potential to improve prehospital hemorrhage control, especially when transport time to definitive care is prolonged.

In general, all hemostatic agents should share a few common attributes. They should be lightweight

and easy to store, carry, and deploy in emergency situations. They should be able to conform to the wound itself, allowing the agent to work where it is needed, especially at deep wound sites where direct pressure alone may not be sufficient or be difficult to apply, such as a femoral artery laceration in the groin. After application, hemostatic agents should be able to withstand the high pressure or flow of a bleeding wound, cause little or no damage to the tissues surrounding the wound site, be easy to remove from the wound, and not spread into the rest of the system as small particles. As of this writing, the prevalent agents on the market are gauzes impregnated with various proprietary clotting agents. Hemostatic dressings are now available over the counter and are being included in commercial bleeding control kits.

Consult your local protocols for guidance on wound packing and the use of hemostatic agents.

Follow the steps in **SKILL DRILL 27-2** to pack a wound.

Tourniquets

A tourniquet is especially useful if a patient has severe hemorrhaging from an extremity injury below the axilla or groin and when other methods of control, such as direct pressure and pressure dressings, are ineffective or inadequate. The laceration or tear of a large artery can cause a patient to exsanguinate in as little as 2 minutes. To avoid this outcome, you must be able to apply a tourniquet in less than 20 seconds.

Skill Drill 27-2 Packing a Wound

Step 1

Expose the wound and wipe away any pooled blood.

Step 2

Pack the wound with hemostatic gauze (preferred), plain gauze, or a clean cloth.

Step 3

Apply steady pressure by pressing with both hands directly on top of the bleeding wound.

For many years, tourniquets were considered a last-ditch effort to be used in patients for whom the choice was between life or the limb. The consensus was that although the tourniquet could stop the bleeding, the result would be the loss of the patient's arm or leg. This belief was based on the historical use of the tourniquet—these devices were first used to stop the blood flow to the extremity prior to an amputation from battlefield injuries. In World War I, tourniquets were also used to stop bleeding from extremities. However, because of the long transport times to definitive care, the

application of the tourniquet was often associated with the loss of the limb.

Since 2005, tourniquets have proven so efficient and easy to use that the US military has issued tourniquets to all field personnel.⁷ A number of commercially available tourniquets are marketed, including the combat application tourniquet (CAT); the special operations forces tactical tourniquet (SOFT-T); the ratcheting medical tourniquet (RMT); and the stretch, wrap, and tuck tourniquet (SWAT-T) (FIGURE 27-8). The CAT uses a strap and buckle system but utilizes a windlass to tighten the strap to control bleeding. The

Controversies

Tourniquet placement has long been a source of controversy. Options include placing the tourniquet “high and tight” on the extremity versus placing it 2 to 3 inches (51 to 76 mm) above the site. Although either may be beneficial when properly secured, there are several considerations for choosing the high-and-tight placement instead of placement just proximal to the injury.

- High-and-tight placement is easier than locating an exact source of bleeding, so it works best for the layperson.
- An artery that has been completely severed can contract back up into the arm or leg, making it difficult to ascertain proper placement just proximal to the injury. Failure to place the tourniquet above the end of the artery will not control bleeding and may result in compartment syndrome as blood collects in the extremity.
- The more distal the injury, the smaller the vessels involved. When the tourniquet is placed 2 to 3

inches (51 to 76 mm) proximal to the wound, it can be more difficult (though still possible) to tighten the tourniquet sufficiently to occlude these smaller vessels.

- Blast wounds may be deeper and more extensive than they originally appear, necessitating a higher placement to ensure bleeding control.
- Care rendered during times of duress, such as an active shooter situation, may not allow time for an actual assessment of the injury or removal of clothing. Placing the tourniquet high and tight negates the need to locate a source of bleeding that may not be readily apparent.
- In patients with obesity, the arms and thighs may be shaped somewhat like a funnel, increasing the risk that a more distally applied tourniquet will slide and become loose. With high-and-tight placement, the patient’s adipose tissue can help hold the tourniquet in place.

RMT uses a ratchet device to apply mechanical pressure, while the SWAT-T serves as a combination of a pressure dressing, wrap, and tourniquet.

The use of commercial tourniquets generally involves the steps in **SKILL DRILL 27-3**. A tourniquet

is typically released at the hospital, but if instructed by medical control, can be released in the field in rare instances. Be aware that bleeding may rapidly return on tourniquet release, so you should be prepared to reapply it immediately, if necessary.

Skill Drill 27-3 Applying a Commercial Tourniquet (Combat Application Tourniquet)

Step 1

Place the tourniquet proximal to the injury. Wrap the band around the limb and fasten it to the buckle.

Step 2

Pull the band tightly and secure the band back on itself.

Step 3

Tighten the rod (windlass) until the bleeding stops.

(continues)

Skill Drill 27-3 Applying a Commercial Tourniquet (Combat Application Tourniquet) *(continued)*

Step 4

Secure the rod inside the clip. Ensure bleeding is still controlled and assess for a distal pulse.

Step 5

Wrap the rest of the band through the clips. Secure the rod with the strap labeled "TK" (for "tourniquet") and the exact time (hour and minute) that you applied the tourniquet.

© Jones & Bartlett Learning.

If a commercial tourniquet is not available, follow these steps to apply a tourniquet using a triangular bandage and a stick or rod:

1. Fold a triangular bandage until it is 4 inches (6 cm) wide and six to eight layers thick.
2. Wrap the bandage around the extremity twice. Choose an area proximal to the injury near the groin or axilla to control the bleeding.
3. Tie one knot in the bandage. Then place a stick or rod on top of the knot, and tie the ends of the bandage over the stick in a square knot.
4. Use the stick or rod as a handle, and twist it to tighten the tourniquet until the bleeding has stopped and distal pulses are no longer palpable; then, stop twisting (**FIGURE 27-9**).
5. Secure the stick in place, and make the wrapping neat and smooth.
6. Write "TK" (for "tourniquet") and the exact time (hour and minute) that you applied the tourniquet on the patient's forehead. Notify hospital personnel on your arrival that the patient has a tourniquet in place. Record this same information on the patient care report form.

As a last resort, you can use a blood pressure cuff as a tourniquet—but keep in mind that blood pressure cuffs with leaks will not hold pressure. Position the cuff proximal to the bleeding point, and inflate it enough to eliminate distal pulses and stop the bleeding. Leave the cuff inflated. Monitor the

FIGURE 27-9 Twist the stick or rod to tighten the tourniquet until the bleeding has stopped and distal pulses are no longer palpable; then, stop twisting.

© Jones & Bartlett Learning.

gauge continuously to ensure the pressure is not gradually dropping, which could allow the bleeding to restart. You may have to clamp the tube leading from the cuff to the inflating bulb with a hemostat (a clamplike instrument used to control bleeding) to prevent loss of pressure.

As an alternative to the standard limb tourniquet, a **junctional tourniquet** is used when the

Words of Wisdom

There is no evidence that applying the tourniquet closer to the site of bleeding is preferable and no reason to believe that normal tissue is at risk by placing the tourniquet too high. Keep in mind that there is the possibility of nerve injury by placing the tourniquets at an unsafe site, such as the proximal leg just below the knee or the proximal forearm just below the elbow, where the common peroneal nerve (leg) or the ulnar nerve (forearm) could be at risk.

hemorrhage is inguinal or axillary. It allows for proximal compression of life-threatening bleeding in areas where standard tourniquet application is not possible. The junctional tourniquet uses a belt system to hold the device in place (either around the hips for an inguinal injury or around the chest for an axilla injury). Using a pump, you then inflate a compression device to put pressure on the deep vessels (**FIGURE 27-10**). The junctional tourniquet, when applied around the hips, can also be used as a pelvic immobilization device, as discussed in the next section.

Whenever you are applying a tourniquet, make sure you observe the following precautions:

- Ensure the tourniquet is proximal to the zone of injury and as close to the groin or axilla as possible.
- Use the widest bandage possible. This will protect the tissues and help with arterial compression.
- Never use wire, rope, a belt, or any other narrow material. It could cut into the patient's skin.
- Make sure the tourniquet is tightened securely.
- Never cover a tourniquet with a bandage. Leave it open and in full view.
- Inform the hospital both in your radio report and in your verbal report on arrival at the ED that a tourniquet has been applied.
- Do not loosen the tourniquet after you have applied it. Hospital personnel will loosen it when they are prepared to manage the bleeding.

Splints

Air Splints

Air splints (commonly known as pressure splints) can control the bleeding associated with severe

FIGURE 27-10 SAM junctional tourniquets can be used for inguinal or axillary hemorrhage control.

© SAM Medical Products®.

FIGURE 27-11 Air splints can also be used to help control bleeding because they act as a pressure bandage for the entire extremity.

© Jones & Bartlett Learning.

soft-tissue injuries, such as massive or complex lacerations, or fractures (**FIGURE 27-11**). They also immobilize the fracture itself. An air splint acts as a pressure dressing applied to an entire extremity rather than to a small, local area.

After you have applied an air splint, be sure to monitor circulation in the distal extremity. Because an air splint is typically inflated to a pressure of approximately 50 mm Hg (so you can still dent the splint with your fingertips), it would not be appropriate to use this device on a patient with arterial hemorrhage: the splint would not actually control the hemorrhage until the patient's systolic blood pressure dropped to the pressure of the splint. Use only approved, clean, or disposable valve stems when orally inflating air splints.

Rigid Splints

Rigid splints can help stabilize fractures as well as reduce pain and prevent further damage to soft-tissue injuries. After you have applied a rigid splint, be sure to monitor circulation in the distal extremity.

Traction Splints

Traction splints are designed to stabilize isolated femur fractures. When traction is applied to the ankle, countertraction is applied to the ischium and groin. This reduces the thigh muscle spasms and prevents one end of the fracture from impacting or overriding the other and realigns the limb. This not only helps to reduce pain, but also helps control hemorrhage and minimize potential vascular and neurologic complications. Be sure to pad these areas well to prevent applying excessive pressure to the soft tissue of the pelvis. After you have applied a traction splint, be sure to monitor circulation in the distal extremity.

Words of Wisdom

Research indicates that a pelvic compression device is an effective method to reduce the width of pelvic ring fractures (**FIGURE 27-12**). Overcompression has not been identified as an issue to date. The restoration of normal pelvic diameter will assist in the control of internal bleeding resulting from the fracture, specifically an open book fracture of the pelvis.

FIGURE 27-12 Pelvic compression devices or binders are meant to provide temporary stabilization and reduce hemorrhage from pelvic bleeding.

© SAM Medical Products®.

Words of Wisdom

Damage control resuscitation (DCR) is a systematic approach to the treatment of the trauma patient with severe injuries. This approach begins with the prehospital care provider and continues through the ED, operating room, and intensive care unit. DCR focuses on maintaining circulating volume, controlling hemorrhage, and correcting the deadly triad of coagulopathy, acidosis, and hypothermia.

Although some tools of DCR such as blood product administration are used by only a few EMS services, many techniques, including rapid assessment; minimizing the use of crystalloid fluids; patient warming; and use of tourniquets, pressure dressings, and hemostatic dressings, are widely available.

Pneumatic Antishock Garment

A **pneumatic antishock garment (PASG)** is an inflatable device that covers the legs and abdomen. Historically, it was used when a patient was exhibiting signs of hypoperfusion. These devices are now rarely used, and you should always follow local protocols.

Controversies

In the 1980s, researchers began to question whether use of the military antishock trousers (MAST/PASG) and IV fluid infusion were actually effective in the treatment of shock.^{11,12} At the time of this writing, the MAST/PASG is rarely applied in the treatment of hemorrhagic shock as the risks of its use likely outweigh any potential benefit based on the medical evidence available. Consult your medical director and regional protocols if you still carry the device.

The few specific instances in which a PASG may be used include the following:

- To stabilize fractures of the pelvis and bilateral femurs
- In some areas, protocols may allow PASG use to control significant internal bleeding associated with fractures of the pelvis and bilateral femurs; however, there is no evidence that this works or is safe for this indication. PASG *does not* replace the need for tourniquet use in severe extremity hemorrhage; use of PASG in these situations may be particularly dangerous.

Pulmonary edema is an absolute contraindication to the use of the PASG.

Hemorrhaging From the Nose, Ears, and Mouth

Several conditions can result in bleeding from the nose, ears, and/or mouth, including the following:

- Skull fracture
- Facial injuries, including those caused by a direct blow to the nose
- Sinusitis, infections, nose drop use and abuse, dried or cracked nasal mucosa, or other abnormalities
- High blood pressure
- Coagulation disorders
- Digital trauma (nose picking)

Epistaxis, or nosebleed, is a common emergency. Occasionally, it can cause enough of a blood loss to send a patient into shock. Keep in mind that the blood you see may be only a small part of the total blood loss. Much of the blood may pass down the throat into the stomach as the patient swallows. A person who swallows a large amount of blood may become nauseated and start vomiting the blood, which is sometimes confused with internal bleeding. Most nontraumatic nosebleeds occur from sites in the septum, the tissue dividing the nostrils.

For a nosebleed from other conditions, such as trauma directly to the nose or bleeding caused by environmental factors such as dry air, apply cold compresses to the bridge of the nose while the patient leans forward. An alternative is to roll gauze and place it under the patient's upper lip. This treatment will generate pressure on the blood supply to the nose and often works within 5 minutes. Check the patient's blood pressure and evaluate for a hypertensive emergency as the cause of epistaxis, especially in older adults. Techniques for controlling epistaxis are covered in Chapter 29, *Face and Neck Injuries*.

Bleeding from the nose or ears following a head injury may indicate a skull fracture. In these cases, you should not attempt to stop the blood flow. This bleeding may be difficult to control. Applying excessive pressure to the injury may force the blood leaking through the ear or nose to collect within the head. This could increase intracranial pressure and possibly cause permanent damage. If you suspect a skull fracture, loosely cover the bleeding site with a sterile gauze pad to collect the blood and help keep

FIGURE 27-13 Bleeding from the ear after a head injury may indicate a skull fracture. Loosely cover the bleeding site with a sterile gauze pad and apply light compression by wrapping the dressing loosely around the head.

© E.M. Singletary, M.D. Used with permission.

contaminants away from the site. There is always a risk of infection to the brain. Apply light compression by wrapping the dressing loosely around the head (**FIGURE 27-13**).

Words of Wisdom

If blood or drainage from the ears or nose contains cerebrospinal fluid (CSF), the dressing will show a staining that resembles a bull's-eye target (**FIGURE 27-14**). Another method that can be used to check for CSF in the blood is the glucometer. Because the CSF has a high glucose content, the glucometer will detect this excess glucose in the blood of a normoglycemic patient.

FIGURE 27-14 When cerebrospinal fluid is present in blood or drainage, a stain in the shape of a target or halo will appear.

Courtesy of Rhonda Hunt.

Internal Hemorrhaging

Because most cases of internal bleeding are rarely fully controlled in the prehospital setting, definitive care includes rapid transport to the ED. Some treatments may be effective in the field depending on the cause of the bleeding. You can usually control internal bleeding into the extremities quite well in the field simply by splinting the extremity, usually most effectively with an air splint.

Treatment of a patient with internal hemorrhaging focuses on the treatment of shock (including prevention of hypothermia), minimizing movement of the injured or bleeding part or region, and rapid transport. Eventually, the patient will likely need a surgical procedure to stop the bleeding. Ultrasonography may be used to locate bleeding in the ED. Ultrasonography is also being used in prehospital environments, particularly the military.

Follow the steps in **SKILL DRILL 27-4** to care for patients with possible internal hemorrhage.

Give the patient nothing by mouth. Insert at least one 18-gauge IV catheter, and administer fluid boluses of 250 mL of normal saline or lactated Ringer solution (provided the patient's lungs are

Controversies

Some trauma surgeons prefer use of lactated Ringer solution over normal saline because lactated Ringer solution may help decrease acidosis in patients with severe hemorrhagic hypovolemia. This belief remains controversial, however, as lactated Ringer solution may also contribute to hyperkalemia in certain trauma patients.¹³

Words of Wisdom

Tranexamic acid (TXA) is another option for controlling internal hemorrhage.¹⁴ TXA works by reducing fibrinolysis by inhibiting the activation of plasminogen to plasmin, which also reduces clot breakdown. Although used predominantly in the military for internal hemorrhage related to trauma, it is now widely used in the civilian sector. It should be considered early, during the assessment of airway, breathing, and circulation (ABC), for those patients presenting with signs of hemorrhagic shock. If TXA is used in your area, follow local protocols and call early for paramedic backup for administration.

YOU are the Provider

Part 5

As the search-and-rescue (SAR) team prepares a Stokes basket, you place a splint on the deformed right leg. You note that the patient still has a weak pulse in the leg; as expected, you are unable to find a pulse in the left upper extremity. You can hear the helicopter in the distance and advise the SAR crew that you need to get the patient moving. Taking care not to pull out the IV lines or disrupt the tourniquet, the patient is placed into the Stokes basket, secured, and carried out approximately one-half mile to the waiting helicopter. After a brief report to the flight crew including the patient's request for pain medication, the patient departs for the local trauma center, a 12-minute flight.

Recording Time: 18 Minutes

Respirations	28 breaths/min, rapid
Pulse	Distal not obtainable, 126 beats/min centrally
Skin	Diaphoretic, cool, pale, and clammy
Blood pressure	82 mm Hg by palpation
Oxygen saturation (SpO₂)	99% on 100% oxygen
Pupils	PERRLA

8. Why was there no pulse in the left upper extremity?
9. What patient information does the flight crew need from you?

Skill Drill 27-4 Managing Internal Hemorrhage

Step 1

Take standard precautions. Maintain the airway with cervical spine immobilization as indicated. Administer supplemental oxygen, and assist ventilation if necessary.

Step 2

Control all obvious external bleeding, and treat suspected internal bleeding using a splint, if possible. Apply a tourniquet for severe bleeding from an extremity that cannot be controlled with direct pressure.

Step 3

Depending on local protocols, if a pelvic fracture is suspected, use a pelvic binder or sheets to bind the pelvic area.

Step 4

Monitor and record vital signs at least every 5 minutes. Keep the patient warm and provide rapid transport.

© Jones & Bartlett Learning.

clear and the patient's condition warrants such a treatment and to a maximum of four doses before online medical consultation) without delaying patient transport. If IV access is unsuccessful or anticipated to be difficult, utilize intraosseous access, if available. Insert an IV line at the scene only if transport is delayed (eg, if the patient is pinned). Establish a second large-bore IV line, if possible. Whenever possible, use warm IV fluids to prevent the patient from becoming hypothermic.

Keep the patient warm. Provide immediate transport and consider paramedic rendezvous for administration of analgesics for pain. Monitor the serial vital signs, and watch diligently for developing shock en route. If the patient shows any signs of shock (hypoperfusion), transport rapidly while providing aggressive management en route. Because a patient in shock is usually emotionally upset, you should provide psychological support as well.

Management of Hemorrhagic Shock

The priorities in treating a patient in hemorrhagic shock are the same as in treating any other patient—with a focus on exsanguinating hemorrhage first (XABC). Always take standard precautions and ensure that the scene is safe. Identify and try to stop any major bleeding, and quickly evaluate the patient's hemodynamic status with a pulse check. Establish and maintain an open airway while maintaining manual stabilization if necessary, assist ventilation and use airway control adjuncts as needed, and continue to monitor the patient's breathing. Keep suction at hand to clear the mouth and pharynx if the patient vomits. Comfort, calm, and reassure the patient in the supine position. Do not allow the patient to eat or drink anything. Splint the patient on a backboard, and, unless necessary to control bleeding at the scene, splint individual extremity fractures during transport as opposed to on scene. If the patient exhibits signs or symptoms of shock, administer supplemental oxygen, keep the patient warm, and prepare for transport.

En route to the ED, insert at least one (preferably two) 18-gauge peripheral IV line, using an over-the-needle catheter. Obtain IV access at the scene only if transport of the patient is delayed. If allowed by protocol, draw blood (two red-top blood collection [Vacutainer] tubes and one purple-top tube) so that hospital personnel may obtain a hematocrit level, determine blood type and cross-match, and perform other tests immediately on your arrival.

Unless your local protocol favors a different resuscitation fluid, administer warm isotonic crystalloids of normal saline in 250-mL increments to maintain the patient's systolic blood pressure at greater than 80 mm Hg (or greater than 90 mm Hg if there is evidence of traumatic brain injury).

Some evidence suggests that titration of systolic blood pressure to 80 to 90 mm Hg is preferred for hemorrhagic shock. This low pressure (ie, permissive hypotension) may allow the blood to clot better and not dislodge clots already formed.¹⁵ However, you must also consider the entire patient before using permissive hypotension. In a patient

with multisystem trauma and traumatic brain injury, the hypotension employed to manage hypovolemia presents severe risks and may potentially result in a lethal outcome. A retrospective observation study reported in the *Journal of Trauma* showed that a single episode of hypotension (systolic blood pressure <90 mm Hg) in patients with severe brain injury was associated with a doubling of mortality and a parallel increase in morbidity rates among survivors.^{16,17} The concern is that the lower blood pressure will not provide adequate cerebral perfusion pressure. This pressure, which is the difference between the MAP and the intracranial pressure, represents the pressure gradient allowing for cerebral blood flow—and with it, oxygen and nutrients into the brain tissue. Without the oxygen and nutrients, the already damaged and delicate brain tissue will suffer secondary injury.

Words of Wisdom

A patient's blood pressure may be the last measurable factor to change in shock. The body has several automatic mechanisms to compensate for initial blood loss and to help maintain the blood pressure. Thus, by the time you detect a decrease in the blood pressure, shock likely will be well developed. This is particularly true in infants and children, who can maintain their blood pressure until they have lost nearly one-half of their total blood volume.

Do not give these patients anything by mouth because they are likely to vomit. Keep the patient at normal temperature, which usually means covering the patient with a blanket—patients in shock are often unable to conserve body heat effectively and are easily chilled. Monitor the level of consciousness, pulse, and blood pressure. In a patient with substantial vasoconstriction, the blood pressure sounds may be difficult to hear. If you can feel a pulse over the femoral artery but not over the radial artery, for example, the systolic blood pressure is probably between 70 and 80 mm Hg, although this technique is minimally accurate for estimating blood pressure.

YOU are the Provider SUMMARY

1. What are some possible hazards in this scene?

A scene such as a hunting accident presents multiple hazards. You are entering an area with hunters who are using firearms. If you are not properly dressed, hunters may confuse you for a deer and shoot you. Do not enter such areas without proper high-visibility clothing or without walking next to someone who is wearing such clothing. Other potential hazards with this scene include the distance you will have to walk to the patient, probably over uneven terrain, and possibly in darkness.

2. Is aeromedical evacuation appropriate with this patient?

Aeromedical evacuation is appropriate for this patient. This patient has uncontrolled arterial bleeding from a gunshot wound. On the basis of these findings and the deformed leg from the fall, this patient has a significant MOI and requires rapid transport to a trauma center.

3. Does this patient require spinal immobilization?

Yes. The patient has a significant MOI that requires spinal immobilization, although he denies having any other injuries than the ones you have located. Based on his femur fracture and the fact that he is in shock, his report of lack of spine pain should be considered unreliable, and spinal immobilization should be instituted.

4. How would you transport this patient one-half mile to the parking area where the helicopter could land?

This patient will have to be carried. On the basis of the injuries and physical findings, there is no way that this patient could or should walk. If there is a local SAR team available, they should be consulted for potential ways to extricate the patient, most likely involving a Stokes-type basket. If a SAR team is unavailable, the patient will need to be secured to a long backboard and carried out.

5. What class of hemorrhaging is occurring in this patient?

This patient is in class 3 or stage 4. At a minimum, this patient has lost 25% of his circulating blood volume, possibly upward of 40%. Prompt recognition and treatment will prevent this from resulting in death.

6. What are the indications for a tourniquet, and when do you remove it?

The indications for a tourniquet are uncontrollable arterial bleeding to an extremity. In this case, because the patient has been applying pressure for 45 minutes and the bleeding has not stopped, the best action is for EMS providers to immediately apply the tourniquet. After application, the tourniquet should not be removed in the prehospital setting.

7. Why should you administer 250-mL boluses until a systolic blood pressure of 80 mm Hg is achieved?

Administering fluid in small increments prevents overhydration and a significant increase in blood pressure. Reassess vital signs and breath sounds after each administration and repeat until the desired goal is reached.

8. Why was there no pulse in the left upper extremity?

The application of an arterial tourniquet would prevent you from detecting a pulse in the left upper extremity. You should be able to palpate a radial pulse in the right upper extremity.

9. What patient information does the flight crew need from you?

The flight crew requires the same information from you that the ED staff does. Particularly, they need to know the MOI, initial findings, treatment (including the time of application for the tourniquet), and vital signs. They will also need to know how much the patient weighs; limits for patient weight vary by aircraft.

Narrative

EMS dispatched to above location for a male reporting a fall with a self-inflicted gunshot wound to the left arm. On arrival, patient found propped against tree, with large pool of blood around him. Pt states he was climbing into tree stand and fell from approximately 14 feet and his rifle discharged. Pt presents with obvious gunshot wound to left bicep, and obvious deformity to right lower leg. Tourniquet applied to left proximal humerus with cessation of bleeding at 0712. Dispatch contacted for helicopter ETA and SAR dispatch. Bilateral 18-gauge IVs established with 250-mL bolus × 4 of normal saline infusing to goal of SBP 80 mm Hg. Non-rebreathing mask applied at 15 L/min. Right leg splinted with positive distal pulse before and after. With help of SAR, patient placed inside of Stokes basket and extricated approximately ½ mile to waiting helicopter. Patient report given to flight crew. EMS remained on scene until the helicopter was safely off the ground

End of report

Prep Kit

Ready for Review

- Perfusion is the circulation of blood in adequate amounts to meet each cell's current needs for oxygen, nutrients, and waste removal.
- Hypoperfusion, or shock, occurs when the cardiovascular system fails to provide adequate perfusion.
- Both internal and external bleeding can cause shock. You must know how to recognize and control both.
- Signs of hypovolemic shock (hypoperfusion) include change in mental status, change in skin color or pallor, weakness, faintness, or dizziness. Key later signs include tachycardia, a weak or rapid pulse, thirst, nausea, vomiting, clammy skin, shallow or rapid breathing, dull eyes or dilated pupils, and decreasing blood pressure.
- The severity of external bleeding is often a function of the types of blood vessels that have been injured. Bleeding from an open artery is usually bright red, spurts, and is difficult to control. Blood from an open vein is much darker and flows steadily. Blood from damaged capillary vessels is dark red and oozes from a wound steadily but slowly.
- Internal bleeding may occur from trauma to any portion of the body. Bleeding into the thorax, abdomen, or pelvis tends to be severe and uncontrolled. Because internal bleeding is not as obvious, you must rely on signs and symptoms to determine the extent and severity of the bleeding.
- Signs of internal bleeding include pain, swelling, tenderness, bruised chest or abdomen, distended abdomen, guarding, hematuria, hematemesis, hemoptysis, melena, hematochezia, and broken ribs.
- The trauma triad of death is a combination of hypothermia, coagulopathy, and acidosis that substantially increases mortality in trauma patients. Closely watch for hypothermia and be sure to keep trauma patients warm.
- During the scene size-up, be sure to follow standard precautions. Depending on the severity of bleeding, this will entail wearing gloves, a mask, eye shield, and possibly a gown.
- Whether or not you can control bleeding, it is a serious emergency. During your primary survey, search for life-threatening external bleeding and control it immediately, before airway and breathing concerns.
- Patients with hemorrhage must be transported. You must determine how fast the transport decision should be made and where the patient should be taken. Consider the priority of the patient and the availability of a regional trauma center.
- Assess and promptly transport any patient who may have internal bleeding, particularly if the MOI is severe and has affected the abdomen, chest, or both.
- Methods for controlling external bleeding include direct, even pressure; pressure dressings and/or splints; and tourniquets. Most cases of external bleeding can be controlled with direct pressure to the bleeding site.
- If direct pressure fails to immediately stop the hemorrhaging, and if you are allowed by local protocol and policy, apply a tourniquet above the level of the bleeding. If a commercial tourniquet is not available, a tourniquet can be improvised with a triangular bandage and a stick or rod.
- Air splints are used to control bleeding associated with severe soft-tissue injuries or fractures. Rigid splints and traction splints are other options used in specific cases.
- Hemostatic agents and wound packing are other methods to control severe hemorrhage.

Hemostatic agents cause enhanced clot formation in a wound site. Wound packing involves placing a gauze into a wound cavity to apply snug pressure to a wound.

- For a nosebleed not associated with skull fracture, apply cold compresses to the bridge of the nose while the patient leans forward. Alternatively, roll gauze and place it under the patient's upper lip. This treatment will generate pressure on the blood supply to the nose and often works within 5 minutes.
- Bleeding from the nose or ears following a head injury may indicate a skull fracture. Do not attempt to stop the blood flow. Loosely cover

the bleeding site with a sterile gauze pad. Apply light compression by wrapping the dressing loosely around the head.

- If you suspect that a patient is bleeding internally or has hemorrhagic shock, maintain the airway, administer supplemental oxygen and assist ventilation as needed, keep the patient still and warm, control all obvious external bleeding, and monitor vital signs at least every 5 minutes. Establish IV access for fluid administration or an intraosseous line if IV access is not successful. Finally, provide rapid transport.

Vital Vocabulary

afterload The pressure in the aorta against which the left ventricle must pump blood; increasing this pressure can decrease cardiac output.

cardiac output (CO) The amount of blood pumped by the heart per minute; calculated by multiplying the stroke volume by the pulse rate per minute.

coagulopathy Any type of bleeding disorder that interferes with the activation or continuation of the clotting cascade or hemostasis.

contusion A bruise without a break in the skin; ecchymosis.

ecchymosis Bruising or discoloration associated with bleeding within or under the skin.

epistaxis Nosebleed.

hematemesis Vomit with blood; can either look like coffee grounds, indicating the presence of partially digested blood, or contain bright-red blood, indicating active bleeding.

hematochezia The passage of stools containing bright red blood, indicating lower gastrointestinal tract bleeding.

hematoma An accumulation of blood in the tissues or in a body cavity.

hematuria The presence of blood in the urine.

hemophilia A congenital abnormality in which the body is unable to produce clots due to a lack of normal clotting factors, resulting in uncontrollable bleeding.

hemoptysis The spitting or coughing up of blood.

hemorrhage A discharge of blood from the blood vessels; bleeding.

hemorrhagic shock A condition in which low blood volume due to massive internal or external bleeding results in inadequate perfusion.

hemostasis Formation of clots to plug openings in injured blood vessels and stop blood flow; the body's natural blood-clotting mechanism.

hemostatic agent Pharmacologic substances used to stop profuse bleeding and that function by absorbing the water component of blood, thereby concentrating the clotting factors, activating platelets, and enhancing the coagulation cascade.

hypovolemic shock A condition in which low blood volume, due to massive internal or external bleeding or extensive loss of body water, results in inadequate perfusion.

junctional tourniquet A bleeding control method used when a traditional tourniquet is not appropriate (inguinal or axillary hemorrhage); can also be used as a pelvic immobilization device.

melena Black, tarry, foul-smelling stools caused by digested blood that has traveled through the digestive tract; caused by upper gastrointestinal bleeding.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

pneumatic antishock garment (PASG) An inflatable device that covers the legs and abdomen; used to splint the lower extremities or pelvis, or

to control bleeding in the lower extremities or pelvis.

preload The precontraction pressure in the heart, which increases as the volume of blood builds up when returned to the heart (venous return); directly affects afterload.

pulse pressure The difference between the systolic blood pressure and the diastolic blood pressure.

shock A condition in which the circulatory system fails to provide sufficient circulation to enable every body part to perform its function; also called hypoperfusion.

tourniquet A bandage or device applied to an extremity to control bleeding, used when a wound continues to bleed despite the use of direct pressure; works by compressing or constricting blood flow.

Chapter 28

Soft-Tissue Injuries

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Soft-Tissue Trauma

Recognition and management of

- Wounds (pp 1316–1329)
- Burns
 - Electrical (pp 1345–1347)
 - Chemical (pp 1343–1345)
 - Thermal (pp 1341–1342)
- Chemicals in the eye and on the skin (p 1343)

Pathophysiology, assessment, and management of

- Wounds
 - Avulsions (pp 1316–1317, 1325)
 - Bite wounds (pp 1316–1318, 1326)
 - Lacerations (pp 1316–1317)
 - Puncture wounds (pp 1318, 1326–1327)
 - Incisions (p 1316)
- Burns
 - Electrical (pp 1345–1347)
 - Chemical (pp 1343–1345)
 - Thermal (pp 1341–1342)
 - Radiation (p 1348)
- Crush syndrome (p 1315)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the skin. (pp 1312–1314)
2. List the functions of the skin. (p 1314)
3. Discuss the pathophysiology of soft-tissue injuries, including closed injuries, open injuries, and burns. (p 1314)
4. Describe the following types of closed soft-tissue injuries: contusion, hematoma, and crush injury. (pp 1314–1315)
5. Describe the following types of open soft-tissue injuries: abrasions, lacerations, avulsions, amputations, bite wounds, penetrating wounds, and blast injuries. (pp 1315–1319)
6. Describe the pathophysiology of wound healing. (pp 1319–1320)
7. Describe the assessment process for patients with a soft-tissue injury. (pp 1320–1321)
8. Describe the relationship between airway management and the patient with closed and open injuries. (pp 1321–1323)
9. Discuss emergency medical care of a patient with a soft-tissue injury. (pp 1323–1324)
10. List the functions of sterile dressings and bandages. (pp 1324–1325)
11. Discuss assessment and management of avulsions, amputations, bite wounds, gunshot wounds, open abdominal wounds, impaled objects, and open neck wounds. (pp 1325–1329)
12. Discuss the pathophysiology of burns, and explain the development of hypovolemic shock. (pp 1329–1330)
13. Define and give the characteristics of superficial, partial-thickness, and full-thickness burns. (p 1331)

14. Explain how the seriousness of a burn is related to its depth and extent. (pp 1331–1334)
15. Explain the steps involved in the assessment of burns. (pp 1334–1339)
16. Describe and discuss the emergency management of burns, including chemical, electrical, thermal, inhalation, and radiation burns. (pp 1339–1348)

SKILLS OBJECTIVES

1. Demonstrate the emergency medical care of closed soft-tissue injuries. (pp 1323–1325)
2. Demonstrate how to control bleeding in an open soft-tissue injury. (pp 1323–1325)
3. Demonstrate the emergency medical care of a patient with an open abdominal wound. (p 1327)
4. Demonstrate how to stabilize an impaled object. (p 1328, Skill Drill 28-1)
5. Demonstrate how to care for a burn. (p 1340, Skill Drill 28-2)
6. Demonstrate the emergency medical care of a patient with a chemical, electrical, thermal, inhalation, or radiation burn. (pp 1341–1348)

Introduction

The skin is the body's first line of defense against external forces and infection. Although it is relatively tough, skin is still quite susceptible to injury. Injuries to soft tissues range from simple bruises or abrasions to serious lacerations, amputations, and burns. Soft-tissue injury may result in exposure of deep structures such as blood vessels, nerves, and bones. In all cases, you must control bleeding, prevent further contamination, and protect the wound from further damage by applying dressings and bandages.

The soft tissues of the body can be injured through a variety of mechanisms. A blunt injury occurs when the energy exchange between the patient and an object is more than the tissues can tolerate, as can happen when a baseball strikes the forearm. A penetrating injury occurs when an object, such as a bullet or knife, breaks through the skin and enters the body. Burns may also result in soft-tissue injuries.

Soft-tissue trauma is a common form of injury. Death resulting from soft-tissue injury is often related to hemorrhage or infection. Uncontrolled hemorrhage can quickly result in shock and death. When the skin barrier is breached, invading pathogens—bacteria, fungi, and viruses—can cause local or systemic infection. Infection can be life or limb threatening, especially in children, older adults, and people with diabetes or other conditions that may compromise the immune system.

Preventing soft-tissue injuries and their associated complications involves simple protective actions. For example, the use of gloves when working

with abrasive materials helps prevent skin injuries. Workplace safety measures to reduce injury include use of safety devices to prevent interaction between machine parts and body parts. Teaching children to avoid (or request help when) using sharp objects also helps prevent injury.

This chapter begins with a review of anatomy and physiology. Then it divides into two parts. Closed and open injuries and their assessment and management are discussed first. Then the assessment and management of burns are discussed in a separate section because they differ from other soft-tissue injuries.

Anatomy and Physiology Review

Skin Structure and Function

The skin, or integumentary system, is the largest organ in the body. It varies in thickness, depending on a person's age and the area the skin covers. The skin of very young and very old patients is thinner than the skin of a young adult. The skin covering the scalp, back, and soles of the feet is quite thick, while the skin of the eyelids, lips, and ears is extremely thin. Thin skin is more easily damaged than thick skin.

The skin has two principal layers: the **epidermis** and the **dermis** (FIGURE 28-1). The epidermis is the tough, external layer that forms a watertight covering for the body. The epidermis contains several layers. The cells on the surface layer of the epidermis are constantly worn away. They are replaced by cells that are pushed to the surface when new cells form in the germinal layer at the base of the epidermis.

FIGURE 28-1 The skin comprises a tough external layer called the epidermis and a vascular inner layer called the dermis. Between the dermis and the underlying muscle and bone is a thick layer of connective tissue known as subcutaneous tissue and a layer of fascia.

© Jones & Bartlett Learning.

The dermis is the inner layer of the skin that lies below the germinal cells of the epidermis. The dermis contains the hair follicles, sweat glands, and sebaceous glands. The sweat glands help cool the body by releasing sweat onto the surface of the skin through small pores, or ducts, that pass through the epidermis. Sebaceous glands produce sebum, the oily material that waterproofs the skin and keeps it supple. Sebum travels to the skin's surface along the shaft of adjacent hair follicles. Hair follicles are small organs that produce hair. There is one follicle for each hair, each connected with a sebaceous

gland and a tiny muscle, the arrector pili, which pulls the hair erect (appearing as goose bumps) whenever a person is cold or frightened.

Blood vessels in the dermis provide the skin with nutrients and oxygen. Small branches reach up to the germinal cells, but no blood vessels penetrate farther into the epidermis. There are also specialized nerve endings within the dermis.

The skin covers all external surfaces of the body. The various orifices in the body, including the mouth, nose, anus, and vagina, are lined with **mucous membranes**. These membranes are similar to skin

YOU are the Provider

Part 1

At 1602 hours, immediately after reporting for your shift, your ambulance is dispatched with the local fire department for a reported explosion at Lake Bronson. En route, the dispatcher reports that you have a 19-year-old man who was pouring gasoline on a barbeque when it flashed and burned him severely. Bystanders are reporting that he is burned "really badly." As you arrive on scene, you find the patient lying on the ground, moaning in pain with his clothing still smoldering on his body. You note full-thickness burns to his chest, both arms, both legs, and his groin. Miraculously, his face appears unscathed. You estimate his weight at 80 kg (178 lb).

1. How do you calculate the percentage of burned area?
2. What classification of burns does this patient have?

in that they provide a protective barrier against invasion of harmful agents, but mucous membranes differ from skin because they secrete a watery substance that lubricates the openings. Therefore, mucous membranes are moist, while skin is dry.

The skin serves many functions. It protects the body by keeping pathogens out and fluids in. The nerves in the skin report to the brain on the environment and on many sensations. It is this nerve pathway connection that allows the body to adapt to environments through responses in the skin and surrounding tissues. The skin is also the body's major organ for regulating temperature. In a cold environment, the blood vessels in the skin constrict, diverting blood away from the skin and decreasing the amount of heat that is radiated from the body's surface. In hot environments, the vessels in the skin dilate. The skin becomes flushed or red, and heat radiates from the body's surface. Sweat glands secrete sweat, which evaporates from the skin's surface and causes a reduction in body temperature.

Any break in the skin allows potentially infectious agents to enter and increases the possibilities of infection, fluid loss, and loss of temperature control. Any one of these problems can cause serious illness and even death.

Skin Tension Lines

The skin is arranged over the body structures in a manner that provides tension. This tautness varies by body region but occurs in patterns known as **tension lines**. Static tension develops over areas that have limited movement, such as the scalp. Lacerations occurring parallel to the skin tension lines may remain closed with little or no intervention. Larger wounds may be pulled open by the normal tension and require closure with sutures, staples, or biodegradable glue. Even small lacerations that lie perpendicular to the tension lines may result in a wound that remains open. Healing occurs more slowly in an open wound, and abnormal scar formation is more likely.

Dynamic tension is found in areas that lie over muscle. This tension varies according to the contraction of the underlying muscle and subsequent movement of the skin. Open injuries to dynamic tension lines interfere with healing because they disrupt the clotting process and the tissue repair cycle, resulting in slowed healing and a tendency toward abnormal scar formation.

Words of Wisdom

The skin's structure includes tension lines, which make the skin become taut with movement. If the skin is cut in a direction that is perpendicular to a tension line (such as over a knee), it will be more difficult to control bleeding in that area because the tension lines will tend to pull the cut open. Splinting injuries helps address this situation and helps to control bleeding.

Pathophysiology of Closed and Open Injuries

Soft tissues are often injured because they are exposed to the environment. There are three types of soft-tissue injuries:

- **Closed injury**, in which soft-tissue damage occurs beneath the skin or mucous membrane but the surface remains intact.
- **Open injury**, in which there is a break in the surface of the skin or the mucous membrane, exposing deeper tissues to potential contamination.
- **Burns**, in which the soft tissue receives more energy than it can absorb without injury. The source of this energy can be thermal heat, frictional heat, toxic chemicals, electricity, or nuclear radiation.

Closed Injuries

Closed soft-tissue injuries are characterized by a history of blunt trauma, pain at the site of injury, swelling beneath the skin, and discoloration. Such injuries can vary from mild to quite severe.

A **contusion**, or bruise, is an injury that causes bleeding beneath the skin but does not break the skin. Contusions result from blunt force striking the body. The epidermis remains intact, but cells within the dermis are damaged, and small blood vessels are usually torn. The depth of the injury varies, depending on the amount of energy absorbed. As fluid and blood leak into the damaged area, the patient may have swelling and pain. The buildup of blood produces a characteristic blue or black discoloration called **ecchymosis** (FIGURE 28-2).

A **hematoma** is a pool of blood that has collected within damaged tissue or in a body cavity

FIGURE 28-2 Contusions, more commonly known as bruises, occur as a result of a blunt force striking the body. The buildup of blood produces a characteristic blue or black discoloration (ecchymosis).

© Jones & Bartlett Learning. Courtesy of MIEMSS.

FIGURE 28-3 A hematoma develops whenever blood vessels are damaged and bleed substantially.

Courtesy of Rhonda Hunt.

(**FIGURE 28-3**). It occurs whenever blood vessels are damaged and bleed rapidly. It may be associated with extensive tissue damage. A hematoma can result from a soft-tissue injury, a fracture, or any

injury to a large blood vessel. In severe cases, such as an aortic transection (torn aorta) or a pelvic fracture, the hematoma may contain more than 1 liter of blood.

A crushing injury occurs when substantial force is applied to the body. The extent of the damage depends on how much force is applied and how long it is applied. In addition to causing some direct soft-tissue damage, continued compression of the soft tissues cuts off circulation, producing further tissue destruction. For example, if a patient's legs are trapped under a collapsed pile of rocks, damage to the leg tissues may continue until the rocks are removed.

In **crush syndrome**, tissue necrosis develops and results in release of harmful products into the bloodstream when the limb is freed from entrapment. The compressing force prevents blood from returning to the injured body part, while by-products of metabolism and harmful products of tissue destruction collect in the part that is crushed. These substances are released into the body's circulation after the limb is freed and blood flow is returned. Cardiac arrest may result almost instantaneously on freeing the limb if substantial amounts of potassium (hyperkalemia) are suddenly returned to circulation. Renal failure is another serious complication that may develop after the release as the kidneys attempt to filter out the harmful products associated with the degradation of dead muscle tissue (a process known as rhabdomyolysis). Life-threatening dysrhythmias may also develop as a result of the acidosis. Intravenous (IV) access should be gained prior to removal to provide a route for medication or rapid fluid replacement, and whenever possible, adequate rehydration should be achieved prior to release of compression, particularly if the victim has been trapped for several hours.

Another form of compression can result from the swelling that occurs whenever tissues are injured. The cells that are injured leak intracellular fluid into the spaces between the cells. If swelling is excessive or occurs in a confined space such as the skull, the tissue pressure will increase to dangerous levels. The pressure of the fluid may become great enough to compress the tissue and cause further damage, especially if the blood vessels become compressed, cutting off blood flow to the tissue. This condition is called **compartment syndrome**. The hallmark sign of compartment syndrome is pain out of proportion to the injury.

Open Injuries

Open injuries differ from closed injuries in that the protective layer of skin is damaged. This can produce extensive bleeding. More important, a break in the protective skin layer or mucous membrane means that the wound is contaminated and may become infected. **Contamination** is the presence of infectious organisms (pathogens) or foreign bodies, such as dirt, gravel, or metal, in the wound. You must address excessive bleeding and contamination in your treatment of open soft-tissue wounds.

As an advanced emergency medical technician (AEMT), you must be prepared to manage several types of open soft-tissue wounds, including abrasions, lacerations, avulsions, amputations, penetrating wounds, bite wounds, and blast injuries.

An **abrasion** is a wound of the superficial layer of the skin, caused by friction when a body part rubs or scrapes across a rough or hard surface. An abrasion typically does not penetrate completely through the dermis, but blood may ooze from the injured capillaries in the dermis. Even though abrasions generally do not result in a considerable loss of blood volume, fluid loss may be substantial when large areas are affected. Known by a variety of names, including road rash, road burn, strawberry, and rug burn, abrasions can be extremely painful because of nerve endings located in this layer of the skin (**FIGURE 28-4**). Even though abrasions are usually superficial, their locations may indicate possible underlying injuries. For example, you should maintain a high index of suspicion that injuries over the flank areas may be the only sign of potential kidney injury.

A **laceration** is a smooth or jagged cut caused by a sharp object or a blunt force that tears the tissue. The depth of the injury can vary, extending through the skin and subcutaneous tissue, even into the underlying muscles and adjacent nerves and blood vessels (**FIGURE 28-5**). Lacerations and incisions may appear linear (in a line) or stellate (irregular) and may occur along with other types of soft-tissue injuries. Lacerations or incisions that involve damaged arteries or veins may result in severe bleeding.

An **avulsion** is an injury that separates various layers of soft tissue (usually between the subcutaneous layer and fascia) so that they hang as a flap (**FIGURE 28-6**). Often, there is substantial bleeding.

A

B

FIGURE 28-4 Abrasions usually do not penetrate completely through the dermis, but blood may ooze from the capillaries. These wounds are typically superficial and result from rubbing or scraping across a hard, rough surface. **A.** Photograph of an abrasion. **B.** Anatomic illustration.

A: © American Academy of Orthopaedic Surgeons; **B:** © Jones & Bartlett Learning.

A completely avulsed body part is considered an **amputation**. We usually think of amputations as involving the upper and lower extremities, but other body parts (eg, scalp, ear, nose, penis, and lips) may also be amputated.

Most people who are bitten by animals do not report the incident to a physician, believing that such bites are not serious. They can be very serious, however. Dogs' and cats' mouths are heavily contaminated with virulent bacteria. You should consider all such bites as contaminated and potentially infected wounds (**FIGURE 28-7**). Occasionally, dog bites result in mangled, complex wounds that require surgical repair.

A

B

FIGURE 28-5 Lacerations vary in depth and can extend through the skin and subcutaneous tissue to the underlying muscles, nerves, and blood vessels. FIGURE 28-7 Small animal bite wounds should be examined at the hospital because these wounds are heavily contaminated with bacteria. **A.** Dog bite. **B.** Cat bite.

A: Dr P. Marazzi/Science Source; **B:** © Charles Stewart, MD, EMDM MPH.

The human mouth, more so than even the dog's or cat's mouth, contains an exceptionally wide range of bacteria and viruses. For this reason, you should regard any human bite that has penetrated the skin as a serious injury. Similarly, any laceration caused by a human tooth can result in a serious, spreading infection (**FIGURE 28-8**).

A **penetrating wound** (or puncture wound) is an injury resulting from a sharp, pointed object, such as a knife, ice pick, or splinter, or from a blunt object traveling at sufficiently high speed, such as a handgun bullet, stick, or metal rod. Objects that are small in diameter leave relatively small entrance wounds, so there may be little external bleeding (**FIGURE 28-9**). However, these objects can damage structures deep within the body and cause unseen bleeding. Additionally, the velocity of the object greatly heightens the potential for increased tissue or organ damage due to cavitation. If the wound is to the chest or abdomen, the injury can cause rapid, fatal bleeding.

An open wound in the abdominal cavity may expose internal organs. In some cases, the organs may even protrude through the wound, an injury called an **evisceration** (**FIGURE 28-10**). An open neck injury can also be life threatening; if the veins of the neck are open to the environment, they may suck in air, resulting in a condition known as **air embolism** (**FIGURE 28-11**). If enough air is sucked into a blood vessel, it can actually block the flow of blood in the lungs and cause cardiac arrest.

As with closed wounds caused by crushing injuries, open wounds caused by crushing injuries

A

B

FIGURE 28-9 Penetrating wounds and impaled objects may cause very little external bleeding but can damage structures deep within the body. **A**. Photograph shows a penetrating wound to the index finger. **B**. Illustration of the soft tissue structures impacted by an impaled object.

may involve damaged internal organs or broken bones, as well as extensive soft-tissue damage (**FIGURE 28-12**). Although external bleeding may be minimal, internal bleeding may be severe, even life threatening. The crushing force damages soft tissues, vessels, and nerves. This frequently results in a painful, swollen, deformed area.

Blast injuries may also often result in multiple penetrating injuries. When a substance is detonated, a solid or liquid is chemically converted into large volumes of gas under pressure with resultant energy release. Propellants, like gunpowder, are explosives designed to release energy relatively slowly compared with high explosives (for example, trinitrotoluene [TNT]), which are designed to detonate rapidly. Explosives such as composition C4

can create initial pressures of more than 4 million pounds per square inch. This generates a pressure pulse in the shape of a spherical blast wave that expands in all directions from the point of explosion. It is imperative for you to conduct a complete primary survey and secondary assessment to determine what type or types of injuries are sustained from a blast injury and treat appropriately. Blast injuries are discussed in Chapter 26, *Trauma Overview*.

Pathophysiology of Wound Healing

Infection

Because the skin serves as an initial barrier against microorganisms, any break in its surface can result in infection. Larger openings and deeper penetrations result in a higher level of risk for the development of an infection. Not only will there be a delay in healing from the infection, but additional complications or systemic infection can result.

Staphylococcus and *Streptococcus* bacteria account for most bacterial skin infections.¹ After pathogens have entered the body tissues, they begin to grow and multiply, although clinical signs of infection may not appear for several days. Visible clues of infection include erythema, pus, warmth, edema, and local discomfort. Red streaks adjacent to the wound indicate that the patient has developed *lymphangitis*, an inflammation of the lymph channels. More serious infections can cause systemic signs, such as fever, shaking, chills, joint pain, and hypotension.

Gangrene

Gangrene is dead tissue. It is caused when blood supply to tissue is interrupted or stopped, known as dry gangrene. It can also be caused by infection (wet gangrene) and direct tissue injury. *Clostridium perfringens* is one example of an anaerobic, toxin-producing bacterium that can result in the development of gangrene. After it enters deeply into tissue, it produces a foul-smelling gas.

Diseases such as diabetes and atherosclerotic peripheral vascular disease can cause gangrene, but traumatic injuries such as burns, frostbite, and wounds can also cause it. Smokers and diabetic patients are more likely to develop symptoms because their peripheral vasculature is compromised.

Suspect gangrene if the patient has chronic risk factors such as diabetes and there is numbness, coolness, or swelling of an extremity. Gangrene may have a bad odor. Late signs of gangrene will be characterized by discoloration of the limb to black, blue, or red. If the gangrene is not treated, the skin will become necrotic and the infection may result in sepsis. Prompt recognition and early, aggressive hospital therapy offer the best chance for reducing morbidity and mortality.

Tetanus

Tetanus is caused by infection with an anaerobic bacterium, *Clostridium tetani* (a member of the same family that causes gangrene). This bacterium produces a potent toxin, which results in painful muscle contractions that are strong enough to fracture bones. In severe cases, laryngospasm and respiratory muscle failure can result in death.

Tetanus has become a rare occurrence because of the availability of a vaccine. In the United States, vaccination against tetanus is part of childhood immunization programs. A booster is needed every 10 years, although an inoculation is typically provided to patients who are injured and have not been immunized in the past 5 years. Given the severity of tetanus, you should ask injured patients about the last time they received a tetanus booster.

Muscle stiffness associated with tetanus may be noted first in the jaw (“lockjaw”) and neck, with progression down the remainder of the body. Early recognition is important because conventional therapy does not result in rapid recovery.

Necrotizing Fasciitis

Fasciitis is inflammation of the fascia. The most serious form of this condition is called **necrotizing fasciitis**, “the flesh-eating disease,” which involves the death of tissue from bacterial infection. Necrotizing fasciitis is caused by various infecting organisms, but most often, group A *Streptococcus*.

Look for a history of vector transmission, insect bites, or puncture wounds (such as from IV drug use). Skin at the site may be reddened and warm; additional symptoms include fever, night sweats, chills, vomiting, and diarrhea. It is important to take standard precautions and properly handle contaminated articles.

Assessment of Closed and Open Injuries

A physician should always evaluate certain wounds. The injuries in **TABLE 28-1** require transport, even if they appear minor.

Assessing closed injuries is much more difficult than assessing open injuries. Therefore, any time you observe bruising, swelling, or deformity, or the patient reports pain, the possibility of a substantial underlying injury should be considered.

The assessment of an open injury is generally easier than the assessment of a closed injury because you can see the injury. Open wounds can be defined as injuries in which there is a break in the surface of the skin or the mucous membrane, exposing deeper tissues to potential contamination. You must use caution to avoid letting a patient’s non-life-threatening gruesome injury distract you from recognizing another injury that is more life threatening.

Scene Size-up

As always, the first aspect to address in any scenario is safety. Ensure that you and your crew have addressed scene hazards and taken the necessary standard precautions: at minimum, gloves and eye protection. Open soft-tissue injuries can be messy. You can often identify patients with an open injury as you approach the scene; however, blood can be hidden under thick, dark clothing such as denim and leather, or in the environment, such as sand, grass, or carpeting. Eye exposures may occur from splashes and droplets at a busy scene; eye protection is required when managing open injuries. Place several pairs of gloves in your pocket for easy

TABLE 28-1 Conditions That Require Transport

 - Vessels
 - Muscles
 - Tendons or ligaments
- Foreign body or cosmetic complications
- Heavy contamination

access in case your gloves tear or there are multiple patients with bleeding. Determine the number of patients and consider whether you need additional or specialized resources on the scene.

When evaluating the mechanism of injury (MOI), maintain a high index of suspicion for internal injuries whenever a significant MOI is present, even if external injuries appear minor. Carefully consider the forces involved as you determine the likelihood of internal damage.

Determine how many patients are involved. Diligently search for ejected patients in the case of a substantial vehicle crash, especially with rollovers.

Primary Survey

When serious trauma is present, soft-tissue injuries take a lower priority than airway control and breathing inadequacy unless they are associated with exsanguinating hemorrhage. *Do not let soft-tissue injuries distract you from life threats that may not be readily apparent.* Rapidly determine whether threats to life are present using the XABCDE mnemonic (eXsanguinating hemorrhage, Airway, Breathing, Circulation, Disability, and Exposure). Note your general impression as you approach the patient.

If visible substantial bleeding is seen, control it quickly using appropriate methods. After you consider the MOI and form suspicions as to where bleeding may occur, expose that part of the body and treat life-threatening bleeding there as well. Patients with visible substantial bleeding or signs of substantial internal bleeding may quickly become unstable. Treatment must be directed toward quickly addressing life threats and providing rapid transportation to the closest appropriate hospital.

As you begin airway assessment, perform manual immobilization if you suspect spinal injury. Check for responsiveness using the AVPU (Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive) scale. Administer high-flow oxygen as needed to maintain oxygen saturation (Spo₂) at 95% or higher. Soft-tissue injuries that result in a flow of blood into the airway can also prove extremely challenging; suction as needed. Immediately correct anything that interferes with airway patency; failure to provide a patent airway can quickly result in the patient's death. Call early for paramedic assistance.

Assess the patient's breathing. Provide oxygen via nonrebreathing mask at 15 L/min or a bag-mask

device and supplementary oxygen for those with inadequate oxygenation or ventilations.

Assess the circulatory status. If no pulse is present, take resuscitative measures. Closed soft-tissue injuries may not always have visible signs of bleeding, and shock may be present. Your assessment of the pulse and skin will indicate how aggressively you need to treat your patient for shock.

If substantial trauma has likely affected multiple systems, perform the 60- to 90-second rapid full-body scan to be sure that you have identified all problems and injuries. When you are done, apply a cervical collar if it is indicated.

Determine whether your patient needs immediate transport or stabilization on scene. Consider whether transport to the closest hospital is appropriate or whether the patient would be better served by transport to a trauma center that might be farther away. Reassess your priority and transport decision as needed.

History Taking

Gather information to determine how the patient was injured.

When time and patient condition permit, determine when the last tetanus booster was given. Record the information on the patient care report and relay it during patient transfer at the hospital.

Make every attempt to obtain a SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) from your patient. Using OPQRST (Onset, Provocation or palliation, Quality, Radiation, Severity, Time of onset) may provide some background on isolated extremity injuries. Any information you receive will be valuable if the patient becomes unresponsive.

Ask the patient about prescribed and over-the-counter medications, paying particular attention to those that interfere with hemostasis. A higher

Street Smarts

Patients with soft-tissue injuries will need emotional care. Patients will likely have concerns about how bruising and scarring may look later. Provide psychological support.

priority should be given to patients taking warfarin or other anticoagulants.

Secondary Assessment

If time allows, perform the secondary assessment to reveal injuries or medical conditions that may have been missed during the primary survey. You may need to perform it en route to the emergency department (ED).

Patients who have hidden internal injuries under a closed soft-tissue injury may have internal bleeding, and their condition may rapidly become unstable. It is important to reassess the vital signs to identify how quickly a patient's condition is changing. Signs such as altered mental status, tachycardia, tachypnea, low blood pressure, weak pulse, and cool, moist, and pale skin indicate hypoperfusion and imply the need for rapid transport and treatment at the hospital. Remember that soft-tissue injuries, even without a significant MOI, can cause shock. The reassessment of your patient's vital signs will give you a good understanding of how well or how poorly your patient is tolerating the injury and whether your interventions have been effective. Use monitoring devices to quantify your patient's oxygenation and circulatory status as needed.

Reassessment

Frequent reassessments of the patient's condition should be made en route to the hospital and in conjunction with any necessary interventions. A patient in stable condition should be reassessed every 15 minutes; a more serious condition warrants reexamination every 5 minutes. Reassessment includes taking and evaluating additional sets of vital signs, checking interventions, and monitoring the patient's condition.

Reassess the airway, breathing, and circulation. Are your interventions still effective? Reassessing a patient with an open soft-tissue injury is extremely important, especially if you did not personally put the bandage on the patient's injury. Frequently, other emergency care personnel may have dressed and bandaged the wound before your arrival. You may need to place additional dressings over the original dressing or bandages. Assess all bandaging frequently. If blood continues to soak through bandages, use additional methods, such as a tourniquet, to control bleeding. Identify and treat changes in the patient's condition.

In your communication and documentation, include a description of the MOI, the position in which you found the patient when you arrived on scene, and an estimate of the amount of blood

YOU are the Provider

Part 2

You quickly remove the patient's smoldering clothing to minimize the burning process, while your partner contacts dispatch and requests a paramedic intercept. By using the rule of nines, you are able to determine that the patient has severe burns over approximately 55% of his body surface area (BSA). The patient is alert and oriented, reporting severe pain (10 on a 10-point scale) throughout his body. He denies any loss of consciousness, just requesting something for the pain. Your partner contacts dispatch again to get an estimated time of arrival of paramedics but is told that none are available.

Recording Time: 1 Minute

Appearance	Anxious
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent; no stridor
Breathing	Nonlabored; 28 breaths/min
Circulation	Strong, rapid radial pulses; skin warm and dry

- What immediate treatment is required for this patient?
- Because this patient is complaining of pain, should you apply moist dressings to cool the burned area?

lost. Include the location and description of any soft-tissue injuries or other wounds you have located and treated, including the size and depth of the injuries. Provide an accurate account of how you treated these injuries. Your ability to communicate and document clearly and accurately enables the physicians and nurses at the hospital to continue quality care.

Emergency Medical Care of Closed and Open Injuries

Closed Injuries

Small contusions require no special emergency medical care. More extensive closed injuries may involve substantial swelling and bleeding beneath the skin, which could result in hypovolemic shock and be life threatening if not appropriately treated.

Severe closed injuries can also damage internal organs. The greater the amount of energy absorbed from the blunt force, the greater the risk of injury to deeper structures. Assess and manage all threats to the ABCs, and be sure to assess all patients with closed injuries for more serious hidden injuries. Remain alert for signs of shock or internal bleeding, and begin treatment of these conditions if necessary, including appropriate oxygen therapy.

Treat a closed soft-tissue injury to an extremity by applying the mnemonic RICES:

- **Rest.** Help the patient rest by keeping the patient as quiet and comfortable as possible. This helps prevent pain and reduce bleeding.
- **Ice.** Apply ice or cold packs to the injured area. Cold slows bleeding by causing blood vessels to constrict, and it also reduces pain.
- **Compression.** Apply firm compression over the injured area; this compresses the blood vessels, decreasing bleeding. Compression may be manual initially but is most effectively applied with an air splint thereafter.
- **Elevate.** Elevate the injured part to a level above the heart to encourage drainage and decrease swelling.
- **Splint.** Apply a splint to an injured extremity. By preventing motion, a splint decreases bleeding. It also reduces pain by immobilizing a soft-tissue injury or an injured extremity. Splinting a fracture helps prevent ongoing soft-tissue injury associated with unstable

sharp bone ends. An air splint provides a double benefit (splinting and compression), although an air splint will not control arterial bleeding.

Extremities that are painful, swollen, or deformed should be splinted. When splinting these types of injuries, remember to assess the patient's pulses and motor and sensory function before and after applying the splint. Do not forget to document the presence or absence of pulses and any changes.

In addition to using these measures to control bleeding and swelling, you should also be alert for signs of developing shock, including tachycardia, tachypnea, cool and/or clammy skin, and a later sign, hypotension. If the patient shows signs of shock, place the patient supine, initiate IV therapy, give high-flow oxygen, keep warm, and provide prompt transport to the hospital.

Open Injuries

Although most open soft-tissue injuries are not serious, if not appropriately treated, many can result in substantial blood loss and even shock. By appropriately treating open soft-tissue injuries, you can minimize the common complications such as bleeding, shock, pain, and infection.

Take standard precautions, and address life-threatening bleeding and then airway and breathing concerns. Then assess the severity of the wound. If the wound is in the chest, upper abdomen, or upper back, cover it with an **occlusive dressing**. Properly position the patient using cervical spine protection, if indicated, and cover the patient to maintain warmth. See Chapter 26, *Trauma Overview*, for more information.

Several methods are available to control bleeding from open injuries. Start with the most commonly used; these methods include the following:

- Direct, even pressure
- Pressure dressings and/or splints
- Tourniquets

It will often be useful to combine these methods. Chapter 27, *Bleeding*, discusses the methods in more detail.

All open wounds are assumed to be contaminated and present a risk of infection. Although it is not always possible to use a sterile technique, you should make every effort to avoid further wound

contamination. Depending on local protocol, irrigate open wounds with normal saline or sterile water to flush out gross contaminants. Chemical burns and contamination should be flushed to remove remaining chemicals. After the wound is irrigated, apply a dressing over the site. This keeps foreign material, such as hair, clothing, and dirt, out of the wound and decreases the risk of infection. To prevent the wound from drying, you may apply sterile dressings moistened with sterile saline solution, if possible, and then cover the moist dressing with a dry, sterile dressing. Finally, neatly wrap a bandage over the dressing

As with closed injuries, splinting can help control bleeding from open soft-tissue injuries as well. Splinting is covered in detail in Chapter 33, *Orthopaedic Injuries*.

Words of Wisdom

Keep in mind that a patient who is bleeding substantially from an open wound is at risk for hypovolemic shock. Be alert for this potential, and treat aggressively to reduce the risk.

Dressing and Bandaging

Dressing and bandaging materials are used to cover wounds, control bleeding, and limit motion. A dressing directly covers a wound and controls bleeding, whereas a bandage keeps the dressing in place.

All wounds require dressing and bandaging. In general, dressings and bandages have three primary functions:

- To control bleeding
- To protect the wound from further damage
- To prevent further contamination and infection

There are many types of dressings and bandages (**FIGURE 28-13**). You should be familiar with the function and proper application of each.

Sterile Dressings

Universal dressings, conventional 4 × 4-inch and 4 × 8-inch gauze pads, and assorted small adhesive-type dressings and soft self-adherent roller dressings

A

B

FIGURE 28-13 A. Many types of sterile dressings are used for covering open wounds, including universal dressings, gauze pads, adhesive dressings, and occlusive dressings.

B. Bandages keep dressings in place and include soft roller bandages, triangular bandages, and adhesive tape. Splints may also be used to hold dressings in place.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

are types of dressings and are used to cover most wounds. Measuring 9 × 36 inches and made of thick, absorbent material, the universal dressing is ideal for covering large open wounds. It also makes an efficient pad for rigid splints. These dressings are available in compact, commercially sterilized packages.

Gauze pads are appropriate for smaller wounds, and adhesive-type dressings are useful for minor wounds. Occlusive dressings (made of petroleum [Vaseline] gauze, aluminum foil, or plastic) prevent air and liquids from entering (or exiting) the wound. They are used to cover open chest wounds, abdominal eviscerations and penetrating wounds above the umbilicus, penetrating back wounds, and open neck injuries.

Words of Wisdom

An occlusive dressing may be made from any material that is nonporous and airtight. For example, plastic wrap from other supplies, the foil wrapper from petroleum gauze, and defibrillation/pacer pads can be used.

Bandages

To keep dressings in place during transport, you can use soft roller bandages, rolls of gauze, triangular bandages, or adhesive tape. Self-adherent, soft roller bandages are probably the easiest to use. They are slightly elastic, which makes them easy to apply, and you can tuck the end of the roll into a deeper layer to secure it in place. The layers adhere somewhat but should not be applied too tightly to one another.

Adhesive tape holds small dressings in place and helps to secure larger dressings. If you have a patient who has a known allergy to adhesive tape, use paper or plastic tape instead.

If an extremity wound continues to bleed despite the use of direct pressure, quickly proceed to using a tourniquet. Tourniquets are discussed in Chapter 27, *Bleeding*.

Complications of Improperly Applied Dressings

Improper application of dressing and bandage material can result in substantial complications. It is important for you to learn how to properly dress a wound in the laboratory, clinical, and field settings to avoid causing harm.

Hemodynamic complications include the possibility for continued bleeding. After a dressing has been placed, it should not be removed because of the risk of disrupting clot formation. If an extremity wound continues to bleed, consider the use of a tourniquet. Frequent reassessments will help prevent unchecked blood loss and hemodynamic complications. Exsanguination is a possibility when direct pressure does not stop blood loss; the same is true for an improperly applied tourniquet. If a tourniquet occludes only venous flow, bleeding may actually increase. Direct pressure is often sufficient to stop blood loss; if not, do not hesitate to apply a tourniquet to an extremity to achieve bleeding control.

Any improperly applied bandage that impairs circulation can result in additional tissue damage or even the loss of a limb. Also, tight dressings may cause pain in a patient who already has an injury. Reassess all interventions frequently. Always check the limb distal to a bandage for signs of impaired circulation or loss of sensation before, during, and after application of the bandage and frequently during transport.

Management of Specific Wounds

Avulsion

If avulsed tissue is hanging from a small piece of skin, the circulation through the flap may be at risk. If you can, replace the avulsed flap in its original position. If an avulsion is complete, wrap the separated tissue in sterile gauze, and take it with you to the ED. This type of avulsion often presents serious infection concerns. Never remove a skin flap from an avulsion, regardless of its size.

Amputation

You can easily control the bleeding from some amputations, such as the fingers, with direct pressure and pressure dressings. If an amputation involves a large area of muscle mass, such as a thigh, there may be massive bleeding. In this situation, you should stop the bleeding, which often requires a tourniquet, and treat the patient for hypovolemic shock. Use the methods described Chapter 27, *Bleeding*.

Surgeons today can often reattach an amputated part (**FIGURE 28-14**). However, correct prehospital

FIGURE 28-14 Amputated parts can often be reattached, so you should make every attempt to find the part and transport it to the emergency department along with the patient.

care of the amputated part is vital to successful reattachment. With partial amputations, make sure to immobilize the part with bulky compression dressings and a splint to prevent further injury. Do not detach any partial amputations because this may make it impossible to reattach the part.

See Chapter 33, *Orthopaedic Injuries*, for a discussion of complete amputations and their prehospital treatment.

Words of Wisdom

Never place an amputated part directly on ice because this may cause frostbite and make reattachment impossible.

Bite Wounds

In the case of an animal bite, place a dry, sterile dressing over the wound, and promptly transport the patient to the ED. If there is gross contamination, consider irrigation of the wound with sterile water prior to dressing. If an arm or leg was injured, splint that extremity. Often, the patient will be extremely upset and frightened, a situation that calls for calm reassurance on your part.

A major concern with small animal bites is the spread of rabies, an acute, potentially fatal viral infection of the central nervous system that can affect all warm-blooded animals. Although rabies is extremely rare today, particularly with widespread inoculation of pets, it still exists. Stray dogs that have not been inoculated can be carriers of the disease, as can any mammal, including squirrels, bats, foxes, skunks, and raccoons. The virus is in the saliva of a **rabid**, or infected, animal and is transmitted through biting or licking an open wound. Infection can be prevented in a person who has been bitten by such an animal only by a series of special vaccine injections that must be initiated soon after the bite. Because animals that have rabies do not always demonstrate symptoms immediately, a person's only chance to avoid the vaccine is to find the animal and turn it over to the health department for observation and/or testing. Refer to your local animal control procedures.

Children, particularly young ones, may be seriously injured or even killed by dogs. The dogs are

not always vicious or rabid; sometimes, the child unknowingly provoked the animal. However, you must assume that it may turn and attack you as well. Therefore, you should not enter the scene until the animal has been secured by the police or an animal control officer. Then you may carry out the necessary emergency care and transport the child to the ED.

The emergency treatment for bites, including animal and human bites, consists of the following steps:

1. Promptly control all bleeding, and apply a dry, sterile dressing.
2. Immobilize the area with a splint or bandage.
3. Provide transport to the ED for surgical cleansing of the wound and antibiotic therapy.

AEMTs are required by law to report all animal bites to the appropriate authority, which is typically the ED physician. Follow local protocols for reporting requirements.

Penetrating Wounds

Assessing the amount of damage a puncture wound has created is difficult and should be reserved for the physician at the hospital. However, because stabbings and shootings often result in multiple penetrating injuries, you must assess patients carefully to identify all wounds. A penetrating object can pass completely through the body; therefore, you should always count the number of penetrating injuries (or holes), especially with gunshot wounds. Entrance wounds and exit wounds are difficult to distinguish in a prehospital setting, especially with the different types of ammunition available. Although entrance wounds are often smaller than exit wounds, it is better to count the number of wounds and leave the distinction between entrance and exit wounds to hospital staff (**FIGURE 28-15**). However, if an entry wound or single open wound is found, look for other wounds.

Gunshot wounds have some unique characteristics that require special care. The amount of damage from a gunshot wound is directly related to the size, shape, and speed of the bullet. Thus, it is important to find out the caliber of gun that was used in the shooting, but do not let this delay patient transport. Sometimes the patient or bystanders can tell you how many rounds were fired. This information can help hospital personnel to better

A

B

FIGURE 28-15 A. An entrance wound from a gunshot may have burns around the edges if the injury occurred at close range. **B.** An exit wound is often larger than an entrance wound and is associated with greater damage to surrounding skin.

care for the patient. Shotgun wounds create multiple pathways of injury and create a larger surface area and volume of tissue damage. However, you should not waste valuable time trying to determine the caliber of weapon. Patient care is the first priority.

Abdominal Wounds

If internal organs are protruding through an open wound, do not touch or move the exposed organs.

A

B

FIGURE 28-16 A. Cover exposed organs with sterile gauze compresses moistened with sterile saline solution. **B.** Place an occlusive dressing over the compresses, and secure it in place by taping all four sides.

© Jones & Bartlett Learning.

Cover the wound with sterile gauze compresses moistened with sterile saline solution, and secure the moist compresses in place with an occlusive dressing (**FIGURE 28-16**). Because the open abdomen radiates body heat effectively and because exposed organs lose fluid rapidly, you must keep the organs moist and warm. If you do not have gauze compresses, you may use moist sterile dressings, covered and secured in place with a dry bandage and tape. Do not use any material that is adherent or loses its substance when wet, such as toilet paper, facial tissue, paper towels, or absorbent cotton. If the patient's legs and knees are uninjured, flex them to relieve pressure on the abdomen. Most patients with abdominal wounds require immediate transport to a trauma center, depending on the local protocol.

Words of Wisdom

A good rule to remember is that anything normally found inside the body needs to be kept moist. Cover eviscerations with moist, sterile dressings.

Impaled Object

Occasionally, a patient will have an object, such as a knife, fishhook, wood splinter, or piece of glass, impaled in the body. To treat this, follow the steps in

SKILL DRILL 28-1.

If the object is very long, cut off (shorten) the exposed portion, first securing it to minimize motion and thus internal damage and pain. After the object is secured and the bleeding is under control, provide prompt transport. Do not try to shorten an

Skill Drill 28-1 Stabilizing an Impaled Object

Step 1

Do not attempt to move or remove the object unless it is impaled through the cheek or mouth and is causing airway obstruction, or it is embedded in the chest or otherwise positioned such that it interferes with cardiopulmonary resuscitation (CPR). In most cases, a surgeon will have to remove the object; removing it in the field may cause more bleeding or damage nerves, blood vessels, or muscles within the wound. Stabilize the object in place using soft dressings, gauze, and/or tape.

Step 2

Remove any clothing covering the injury. Control bleeding with direct pressure, and apply a bulky dressing to stabilize the object. Some combination of soft dressings, gauze, and tape may be effective, depending on the location and size of the object. To prevent further injury, manually secure the object by incorporating it into the dressing.

Step 3

Protect the impaled object from being bumped or moved during transport by taping a rigid item such as a plastic cup, a section of a plastic water bottle, or a supply container over the stabilized object and its bandaging.

FIGURE 28-17 Cover neck wounds with an airtight dressing, and apply manual pressure. Do not compress both carotid arteries at the same time because this may impair circulation to the brain.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

impaled object unless it is extremely cumbersome (such as a fence post impaled in the chest); any motion of the object may damage surrounding tissues.

Words of Wisdom

There are only two exceptions to the rule of not removing an impaled object: if the object is through the cheek and interferes with the airway and if the object is in the chest and interferes with chest compressions.

Open Neck Wounds

An open neck injury can be life threatening. If the veins of the neck are open to the environment, they may suck in air, potentially causing an air embolism and cardiac arrest. To control bleeding and prevent the possibility of an air embolism, cover the wound with an occlusive dressing. Apply manual pressure, but do not compress both carotid arteries at the same time; if you do, circulation to the brain will be impaired (**FIGURE 28-17**). Secure a pressure dressing over the wound by wrapping roller gauze loosely around the neck and then firmly through the opposite axilla.

Burns

Each year in the United States, approximately 486,000 burn injuries require medical attention, and there are 3,275 fire/burn/smoke inhalation

Assessment Pearls

- Call early for paramedic backup when burned patients present with signs of possible airway involvement, such as stridor, carbonaceous sputum, soot on the face, and singed nasal hairs.
- Use dry dressings on burns when more than 10% of the BSA is involved. The only exception is when there is still active burning and wet dressings or water are used to stop the burning process.
- Maintain a high index of suspicion when treating pediatric and geriatric patients who are burned. Neither population is able to compensate well.
- Suspect compartment syndrome when a patient has an injury to an extremity with pain that is out of proportion to the visible injury. This is a classic sign.
- Avoid tunnel vision! Soft-tissue injuries and burns can be distracting. Pay attention to the MOI and the potential for underlying trauma.
- If the pulse in an extremity cannot be palpated after a splint is applied, remove the splint and reassess for the presence of a pulse.
- Always use occlusive dressings for open neck injuries.
- Do not waste time on scene trying to start an IV line in a burned patient; it can be done en route or at the hospital. It is more important to get the patient to definitive care.

deaths.² Burns are also among the most serious and painful of all injuries. A burn occurs when the body, or a body part, receives more thermal, electrical, or chemical energy, or is exposed to more radiation, than it can absorb without injury.

Pathophysiology

Burns are sometimes not simply isolated soft-tissue injuries but also systemic injuries. Initially, there is a release of catecholamines (epinephrine and norepinephrine) in response to the pain and stress of the situation. Because of overall vasoconstriction, there is a decrease in blood flow to the injured area. During the next several hours, there follows a fluid shift phase that is usually not seen in the prehospital setting. Damaged cells in the area release vasoactive substances, creating an inflammatory response and increasing capillary permeability. Massive edema is the result of fluid shifting from the intravascular space into the extravascular space. Sodium moves

into the injured cells, creating even more fluid loss as osmotic pressure increases. This also causes a loss of electrolytes and may result in hypovolemia.

Tissue damage reduces the ability of the body to regulate its core temperature. Fluid seeps into the damaged area where it is exposed to surface air, causing evaporation and loss of heat. In severe burns, this can rapidly result in hypothermia.

As fluid volume decreases, less oxygen is transported to the tissues and organs, resulting in hypoxia, acidosis, and possibly anoxia. Hypovolemia causes a decrease in cardiac output, resulting in hypotension. To maintain homeostasis, the body responds with vasoconstriction to elevate blood pressure and increase perfusion to vital organs and with tachypnea to offset the metabolic acidosis and hypoxia. The burn process may result in renal failure, liver failure, dysrhythmias, and heart failure.

As the burn destroys skin, a tough leathery substance known as **eschar** is produced. Eschar is not pliable like normal skin. As edema increases, pressure is exerted on the underlying structures. A circumferential eschar around an extremity can cause circulatory compromise and may require an escharotomy—a surgical incision to relieve the pressure and restore circulation—after the patient arrives at the ED. A circumferential burn may result in compartment syndrome. The skin is unable to stretch, resulting in eventual compression and decreased or absent circulation in the tissues below. If the burn is around the thorax, tidal volume and chest excursion may be dramatically reduced by the eschar formation, resulting in ventilatory insufficiency.

Hypovolemic Shock

Burns can affect the cardiovascular, respiratory, renal, gastrointestinal, hematologic, and endocrine systems. The most important systemic response to substantial burn trauma is hypovolemic shock.

Hypovolemic shock occurs because of two types of injuries: fluid loss across damaged skin and a series of volume shifts within the rest of the body. Capillaries become leaky, allowing intravascular volume to ooze out of the circulation and into the interstitial spaces. The cells of normal tissues then take in increased amounts of salt and water from the fluid around them. As blood pressure decreases, the body responds with tachycardia and

vasoconstriction, which limits blood flow further and continues the shock cycle. A variety of chemical mediators are released that may cause additional damage and worsen the chain of events. Depending on the nature of the burn, coagulation disorders may cause the patient's blood either to clot more easily, resulting in emboli, or to fail to clot, causing excessive bleeding (disseminated intravascular coagulation). Coagulation disorders are discussed in Chapter 21, *Endocrine and Hematologic Emergencies*.

Hypovolemic shock involves the entire body, not just the area burned. You may have experienced sunburn over a reasonably large surface area, such as your back. In addition to the skin-related discomfort from the sunburn, you may have developed chills and nausea and felt sick as a result of the fluid shifts and electrolyte disturbances. This reaction is a mild form of burn shock. Just as in other forms of shock, these changes limit the effective distribution of oxygen and glucose to the body's tissues and hamper the circulation's ability to remove waste products from both healthy and damaged tissues. Adequate fluid resuscitation is essential to avoid the devastating consequences of burn shock.

Complications of Burns

There are several complications that can result from a burn injury, all of which can be life threatening. The skin serves as a barrier between the environment and the body. When a person is burned, this barrier is destroyed; the victim is now at a high risk for infection, hypothermia, hypovolemia, and shock. Burns to the airway are of substantial importance because the damaged mucosa in the hypopharynx can swell and rapidly result in complete airway obstruction. Circumferential burns of the chest can compromise breathing. Circumferential burns of an extremity can result in compartment syndrome, resulting in neurovascular compromise and irreversible damage if not appropriately treated. If you suspect any complications, consider calling for paramedic backup.

Burn Zone

Historically, burn wounds have been described by three pathologic progressions, known as zones, which radiate from the central zone of greatest damage. Skin nearest the heat source suffers the

most profound cellular changes. The central area of the skin that suffers the most damage is called the **zone of coagulation**. There is little or no blood flow to the injured tissue in this area. The peripheral area surrounding the zone of coagulation has decreased blood flow and inflammation; it is known as the **zone of stasis**. This area may undergo tissue necrosis within 24 to 48 hours after the injury, particularly if perfusion is compromised by burn shock. Last, the **zone of hyperemia** is the area least affected by the thermal injury. In this area, cells will typically recover in 7 to 10 days. Similar to the case with a myocardial infarction or stroke, the role of treatment is to salvage as much of the injured tissue as possible by improving perfusion and limiting the secondary changes that turn damaged tissue into dead tissue.

Burn Depth

Burn formation is a progressive process: the greater the heat energy, the deeper the wound. Superficial burns may injure only the epidermis, whereas deeper burns extend into or through the dermis, subcutaneous tissue, muscle, and bone.

While evaluating the patient's burns, you must approximate the extent of the burn, or the total body surface area (TBSA) burned. The severity of burns is classified according to the depth: superficial (first degree), partial thickness (second degree),

and full thickness (third degree) (**FIGURE 28-18**). As an AEMT, you must be able to identify each of the following:

- **Superficial burns** (first degree) involve only the top layer of skin, the epidermis. The skin turns red but does not blister or burn through to the dermis. The burn site is painful. Sunburn is a good example of a superficial burn.
- **Partial-thickness burns** (second degree) involve the epidermis and some portion of the dermis. These burns do not destroy the entire thickness of the skin, and the subcutaneous tissue is not injured. Typically, the skin is moist, mottled, and white to red. Blisters are common. Partial-thickness burns cause intense pain.
- **Full-thickness burns** (third degree) extend through all skin layers and may involve subcutaneous layers, muscle, bone, and internal organs. The burned area is dry and leathery and may appear white, dark brown, or even charred. This rough area is known as eschar. Some full-thickness burns feel hard to the touch. Clotted blood vessels or subcutaneous tissue may be visible under the burned skin. If the nerve endings have been destroyed, a severely burned area may have no feeling. However, the surrounding, less severely burned areas may be extremely painful.

YOU are the Provider

Part 3

You reassure him that you are doing the best you can and will get him to the hospital as quickly as possible. You and your partner lift the patient to the stretcher and secure him into the back of the ambulance. While your partner obtains vital signs and gives the patient 100% oxygen via nonrebreathing mask, you attempt to establish IV access.

Recording Time: 8 Minutes

Respirations	Normal; 26 breaths/min
Pulse	Strong and rapid; 137 beats/min
Skin	Warm and dry
Blood pressure	102/64 mm Hg
Oxygen saturation (SpO₂)	100% oxygen via nonrebreathing mask at 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. Should you attempt IV access through the burned area?
6. How would you calculate the amount of fluid the patient requires?

FIGURE 28-18 Classification of burns according to depth. **A.** Superficial, or first-degree, burns involve only the epidermis. The skin turns red but does not blister or burn through to the dermis. **B.** Partial-thickness, or second-degree, burns involve some of the dermis, but they do not destroy the entire thickness of the skin. The skin is mottled, white to red, and often blistered. **C.** Full-thickness, or third-degree, burns extend through all layers of the skin and may involve subcutaneous tissue and muscle. The skin is dry, leathery, and often white or charred. **D.** Illustrations of superficial, partial-thickness, and full-thickness burns, showing the extent of internal damage.

A: © Amy Walters/Shutterstock; **B:** © John Radcliffe Hospital/Science Source; **C:** © E.M. Singletary, M.D. Used with permission; **D:** © Jones & Bartlett Learning.

Additional categories of burns exist, such as fourth-, fifth-, and sixth-degree burns, for describing deeper destruction into tissue, muscle, and bone.

A pure full-thickness burn is unusual. Severe burns are typically a combination of superficial, partial-thickness, and full-thickness burns. Superficial burns heal well without scarring. Small partial-thickness burns also heal without scarring. However, deep partial-thickness burns and all full-thickness burns are susceptible to scarring and may be best managed surgically.

It may be impossible to accurately estimate the depth of a particular burn. Even experienced burn specialists sometimes underestimate or, more commonly, overestimate the extent of a particular burn. Do not spend a substantial amount of time categorizing burns in the field; the hospital needs to know the approximate type of burn, and you need to generally categorize the burn to properly determine the level of care that the patient requires. These burns will look different in a few hours, as the damage evolves, and you should not

Words of Wisdom

Suspect substantial airway burns if there is singed hair within the nostrils, soot around the nose and mouth, hoarseness, or hypoxia.

waste time carefully categorizing something that will rapidly change.

Burn Severity

To assess a burn, you must consider its severity. The seriousness of a burn may influence medical control's choice of a treatment facility. Five factors will help you to determine the severity of a burn (the first two factors are the most important; after gauging these, ask yourself the remaining questions):

1. What is the depth of the burn?
2. What is the extent of the burn?
3. Are any critical areas (face, upper airway, hands, feet, genitalia) involved? Also included in critical areas are any circumferential burns, which are burns that go completely around a body part such as an arm, foot, or chest.
4. Does the patient have any preexisting medical conditions or other injuries that could be complicated by the burn injury?
5. Is the patient younger than 5 years or older than 55 years?

If the answer to any of these last three questions is yes, you should upgrade the burn's classification.

TABLE 28-2 shows burn severity classifications.

Keep in mind that burns to the face are of particular importance because of the potential for airway involvement. In addition, burns to the hands or feet or over joints are also considered serious because of the potential of loss of function as a result of scarring.

Burn Extent

The fastest and most commonly used mechanism of calculating the TBSA burned is the **rule of nines**, which is based on dividing the body into 11 sections, each representing approximately 9% of TBSA.³ The provider adds the portions of the body with burns to obtain the TBSA affected by the burn injury. Because our proportions change as we grow, different rules of nines apply to infants, children, and adults (**FIGURE 28-19**).

TABLE 28-2 Classification of Burn Severity

Burn Classifications	Criteria
Major burns	• Burns involving the hands, feet, face, major joints, or genitalia, or circumferential burns of other areas • Full-thickness burns covering more than 10% of TBSA • Partial-thickness burns covering more than: • 25% of TBSA if age 10–50 y • 20% of TBSA if younger than 10 y or older than 50 y • Burns associated with respiratory injury (smoke inhalation or inhalation injury) • Burns complicated by fractures or trauma • High-voltage electrical burns • Chemical burns • Burns on patients younger than 5 years or older than 55 years that would be classified as moderate on young adults
Moderate burns	• Full-thickness burns involving 2% to 10% of TBSA (excluding hands, feet, face, genitalia, and upper airway) • Partial-thickness burns covering: • 15%–25% of TBSA if age 10–50 y • 10%–20% of the TBSA if younger than 10 y or older than 50 y • Superficial burns covering more than 50% of TBSA • Low-voltage electrical burns • Major burn characteristics absent
Minor burns	• Full-thickness burns covering less than 2% of TBSA • Partial-thickness burns covering: • Less than 15% of TBSA if age 10–50 y • Less than 10% of TBSA if younger than 10 y or older than 50 y • Superficial burns covering less than 50% of TBSA • Major burn characteristics absent

Abbreviation: TBSA, total body surface area

Data from: Pappas-Taffer L. Burns. In: Ferri FF, ed. *Ferri's Clinical Advisor* 2017. Philadelphia, PA: Elsevier; 2017: 219–221; and Tintinalli JE, Stapczynski JS, Ma OJ, et al. *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*. 8th ed. New York, NY: McGraw-Hill; 2016.

FIGURE 28-19 The rule of nines is a quick way to estimate the amount of surface area that has been burned. It divides the body into 11 sections, each representing approximately 9% of the total body surface area. The segments differ for infants, children, and adults.

© Jones & Bartlett Learning.

Another quick way to estimate the surface area that has been burned is to use a technique known as the **rule of palms**, also called the rule of ones. This assessment uses the size of the patient's palm (including the fingers) to represent approximately 1% of the patient's TBSA. This calculation is helpful when the burn covers less than 10% of TBSA or is irregularly shaped.

Assessment of Burns

Although a burn may be the patient's most obvious injury, you should always perform a complete assessment to determine whether there are other, more

serious injuries. When you are assessing a burn, you will need to classify it to determine its severity. Assessment of a patient with burns is essentially the same as with any other trauma patient. Again, you must use caution to avoid being distracted by dramatic burn injuries and, thus, possibly overlooking other potential life threats that require treatment.

Scene Size-up

As you arrive on scene, observe the scene for hazards and threats to the safety of you and your crew, bystanders, and the patient. Ensure that the factors that resulted in the patient's burn injury do not pose a

hazard to you and your crew. Is the electricity turned off? Is the chemical leak secure? Has the fire been extinguished? Is there any potential for violence?

When possible, determine the type of burn that has been sustained and the MOI. Patients with burns can be a challenge to treat physically and emotionally. It is easy to become overwhelmed by the sights, sounds, and smells of burn victims.

Assess the scene for any environmental hazards. If the patient is the victim of a lightning strike, is the weather still a threat to your safety? Wear gloves and eye protection when treating any patient with burns and gowns when serious injuries are expected. Determine the number of patients; the possibility for multiple patients increases if you are responding to a lightning strike or a vehicle crash. At vehicle crashes, ensure that there are no energized electrical lines or leaking fuel in the area where you will be working. If you determine that the power company, the fire department, or paramedic units are needed, call for additional resources early. Remember, a patient with burns may also be a trauma patient. Consider the potential for spinal injuries, inhalation injuries, and other injuries.

Special Populations

Burns to children are generally considered more serious than burns to adults. This is because infants and children have more surface area relative to total body mass, which means greater fluid and heat loss. In addition, children do not tolerate burns as well as adults do. Children are also more likely to experience shock, hypothermia, and airway difficulties because of the unique differences associated with their ages and anatomy.

Some burns in infants and children result from child abuse. The classic burn resulting from deliberate immersion involves the hands and wrists, as well as the feet, lower legs, and buttocks. Similarly, burns around the genitals and multiple cigarette burns should be viewed as possible abuse. Report all suspected cases of abuse to the proper authorities. See Chapter 36, *Pediatric Emergencies*, for more information.

Primary Survey

The primary survey includes a rapid full-body scan of the patient to identify and manage life-threatening concerns and to assist with transport decisions.

As you approach a burned trauma patient, simple clues can help identify how serious the injuries are and how quickly you need to assess and treat them. A patient who greets you with a hoarse voice or is reported to have been in an enclosed space with a fire or intense heat source has indications of a significant MOI. The presence of stridor means your patient's airway is substantially swollen and can signal impending complete airway obstruction. Similarly, if the patient has singed facial hair, eyebrows, or nasal hair, your initial general impression might indicate that the patient has a potential airway and/or breathing problem. If the burn is associated with a fall, blast, or other trauma, the patient might also present with musculoskeletal injuries.

Child abuse and elder abuse are unpleasant situations to handle. Unfortunately, they are often situations that involve burns. As you enter a scene where burns are involved, be suspicious of clues that may indicate abuse.

The burned patient you encounter may have graphic injuries; however, stay focused on the primary survey. As you begin the primary survey, always consider the need for manual spinal stabilization.

Check for responsiveness using the AVPU scale. Assess a patient's mental status by asking the patient about the chief complaint. An unresponsive patient may indicate a life-threatening condition. In all patients whose level of consciousness is less than alert and oriented, administer high-flow oxygen as needed via a nonrebreathing mask or bag-mask device, and provide immediate transport to the ED.

Substantial bleeding is an immediate life threat and takes priority over airway and breathing concerns. If the patient has obvious life-threatening bleeding, it must be controlled quickly. Often, shock develops in burned patients. Treat the patient for shock as quickly as possible, according to local protocol, including covering to prevent heat loss. This is important because the damaged skin has only a limited ability to regulate body temperature.

Ensure that the patient has a clear and patent airway. If the patient is unresponsive or has a substantially altered level of consciousness, consider inserting a properly sized oropharyngeal or nasopharyngeal airway.

The following are signs of airway involvement in a burn patient:

- Hoarseness
- Cough
- Stridor
- Singed nasal or facial hair
- Carbon in the sputum
- History of burn in an enclosed space

Heavy amounts of secretions and frequent coughing may also indicate a respiratory burn. A patient with signs and symptoms of airway burns can rapidly lose airway patency as a result of tissue swelling. Although rare, laryngeal edema can develop with alarming speed in burn patients, especially in infants and children. Request a paramedic rendezvous with providers capable of performing intubation or other interventions as soon as possible, and be alert to signs of impending airway closure.

Quickly assess for adequate breathing. Inspect and palpate the chest wall for DCAP-BTLS (Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, Swelling). Check for clear and symmetric breath sounds, and provide high-flow oxygen or assisted ventilations using a bag-mask device as needed, depending on the level of consciousness and breathing rate and quality in your patient. Patients with burns are trauma patients. Evaluate and treat them for spinal injuries and airway problems concurrently. How you open the airway depends on whether a neck injury is suspected. Do the circumstances surrounding the MOI suggest a possible spinal injury?

Quickly assess the pulse rate and quality, and determine perfusion based on the patient's skin condition, color, temperature, and capillary refill time.

If the patient you are treating has an airway or breathing problem, substantial burn injuries, substantial external bleeding, or signs and symptoms of internal bleeding, consider quickly transporting the patient to the hospital for treatment. A rendezvous with paramedics may be appropriate for patients with moderate or severe burns and burns of the airway or **inhalation injury**. Paramedics can treat these patients with endotracheal intubation and analgesics for pain. These problems can progress so rapidly; immediate paramedic backup can make the difference between life and death. Provide rapid transport to the closest, most appropriate facility. If a burn center is not available, a Level I trauma center is the next-best option.

Words of Wisdom

Patients with preexisting lung disease may have bronchospasm after even relatively minor exposure to smoke. These patients may respond well to inhaled beta-2 agonists.

History Taking

Investigate the chief complaint or history of present illness. The first complaint in a patient with a burn injury is usually pain at the site. Next, be alert for signs or symptoms of other injuries due to the MOI.

Obtain a medical history and be alert for injury-specific signs and symptoms and any pertinent negatives, such as no pain. Typical signs of a burn are redness, swelling, blisters, or charring. Typically, symptoms include pain and/or burning at the injury site. Regardless of the type of burn injury, it is important to stop the burning process, apply dressings to prevent contamination, and treat the patient for shock.

Obtain a SAMPLE history from your patient. In addition, ask the following questions of a patient with burns:

- Are you having any difficulty breathing?
- Are you having any difficulty swallowing?
- Are you having any pain?

When you are assessing a patient with burns, check to see whether the person has an emergency medical identification device such as a wallet card, necklace, or bracelet, or ask the patient or a family member about preexisting conditions, which may increase the chances of a poor outcome. Remember that the environment, bystanders, and medical identification devices may provide important clues about your patient's condition.

Secondary Assessment

At this point, you will conduct a more detailed physical examination, or focused examination of the patient depending on the injury, to reveal any additional injuries. In some cases in which the patient is critically injured or the transport time is short, you may not have time to conduct a secondary

assessment. In other cases, the secondary assessment may occur en route to the ED.

Quickly assess the patient from head to toe, looking for DCAP-BTLS to ensure that you have found all problems and injuries. Make a rough estimate, using the rule of nines, of the extent of the burned area to report to medical control. Determine what classification of burns the victim has sustained. The patient may or may not report pain depending on the amount of nerve damage. Before packaging your patient, determine the severity of the burns the victim has sustained, as described earlier. Follow your local protocols for criteria for transport to a burn center. Package the patient for transport based on your findings. Remember to immobilize your patient for spinal injuries as appropriate.

When assessing the respiratory system of a burned patient, look specifically for the following findings:

1. Soot around the mouth
2. Soot around the nose
3. Singed nasal hairs

Listen to breath sounds with a stethoscope. Breath sounds should be clear and equal bilaterally, anteriorly, and posteriorly. Determine the patient's rate and quality of respiration. Finally, assess the chest for DCAP-BTLS and asymmetric chest wall movement. Patients with burns who present with any types of airway problems should be considered critical.

If you find substantial bleeding during the secondary assessment, as always, controlling it and treating for shock are the highest treatment priorities since these are immediate life threats. Non-life-threatening bleeding, such as in abrasions, can be bandaged later in your assessment as necessary.

Assess the patient's neurologic system to formulate baseline data for further decisions on patient treatment.

Assess the musculoskeletal system by performing a detailed full-body exam if time permits. Specifically look for the following features:

- In the head, be alert for raccoon eyes, Battle sign, and/or drainage of blood or fluid from the ears or nose. Check for singed nasal or facial hair, burns or swelling of the face or ears, or burns or swelling in the mouth. If the

patient sustained electrical injury, examine the scalp for signs of entrance or exit wounds.

- In the neck, check for jugular venous distention and tracheal deviation. Be alert for patients with a stoma or tracheostomy. Also note any circumferential burns around the entire neck; these can impair breathing and circulation.
- In the chest, check for burns that encircle the entire chest, which can impair normal chest rise.
- In the abdomen, feel all four quadrants for tenderness or rigidity. If the abdomen is tender, expect internal bleeding.
- Look for burns that encircle an extremity, as they can impair circulation. If the patient sustained an electrical injury, assess thoroughly for entry or exit burn wounds. This should include the axilla and the area between digits. Record pulse and motor and sensory function.
- Examine the posterior surface of the body, as large burns or electrical exit burns may be located in this area.
- In the pelvis, check for stability.

Obtain an early set of vital signs to determine how your patient is tolerating the injuries while en route to the hospital. These can be obtained in the ambulance on the way to the hospital, decreasing the delay to definitive care in a patient with moderate to severe burns. Because shock is often pronounced in a burned patient, blood pressure, pulse, and skin assessment for perfusion are important vital signs to obtain.

Finally, use monitoring devices, including oxygen saturation monitors and carbon monoxide monitors when available, to quantify oxygenation and circulatory status.

Reassessment

Repeat the primary survey, and reassess the patient's vital signs. Reassess the patient's chief complaint. Reevaluate interventions and treatment you have provided to the patient, particularly those used to treat shock. Identify and treat any changes in the patient's condition.

Provide hospital personnel with a description of how the burn occurred. Many times, the ED staff can determine the appropriate diluent for chemical burns or calculate appropriate treatments for

Special Populations

Escaping from a fire can be difficult for children. Although the percentage of fatal outcomes for children younger than 5 years involved in a house fire decreased from 18% in 1980 to 6% in 2015,⁴ research suggests that young children are not as effectively awakened by smoke detectors, and they are often disoriented immediately after waking. Young children are also more likely to sustain severe scald injuries. Children's thin skin and delicate respiratory structures are more easily damaged by thermal insults than are those of older children and adults.

In children, fluid resuscitation may be more challenging because of their increased body surface-to-weight ratio. Therefore, children may require more fluid per kilogram compared with adults. You may start by providing fluids based on the Consensus formula in children only to find that medical control orders additional fluids for major burns. Also, because of their relatively poor glycogen stores, children may require dextrose-containing solutions earlier than adults do. Blood glucose monitoring should be routinely performed in seriously burned children, particularly in the context of any decrease in the level of consciousness.

Burns may raise the suspicion of child abuse. Pay careful attention to the MOI, and relay this information to the hospital staff.

Approximately 1,300 older adults die of fire-related causes each year, which represents a 2.5-fold greater likelihood of fire-related deaths in this population as compared with the general population.⁵ Many older adults smoke (more than 8.4% of US adults older than age 65 years smoke cigarettes⁶), and smoking is the leading cause of fires that result in the death of older adults. Burns from fires caused by smoking while wearing a supplementary oxygen supply are the leading sentinel event in home health care. Cooking fires represent another distinct hazard to older adults, who may be less able to smell a gas leak or a fire in the kitchen. Older adult patients are also particularly sensitive to respiratory insults. Relatively small fires can produce toxic fumes before detection or suppression devices are activated.

Older adult patients may also have poor glycogen stores, so their blood glucose levels should be checked to assess for hypoglycemia if there is any change in mental status or decreased level of consciousness. Although fluid resuscitation is important, pulmonary edema is more likely to develop in older patients. Routinely assess breath sounds in older adults who have burns.

YOU are the Provider

Part 4

By using the Consensus formula, you calculate that the patient requires 8,800 mL of fluid during the first 24 hours and 4,400 mL during the first 8 hours. Seeing no readily identifiable veins in unburned areas, you establish bilateral large-bore IV lines in each antecubital fossa. With an estimated 20-minute transport time, you administer a 500-mL bolus in each IV line. You advise your partner that this patient requires emergency transport, and you begin your way to the hospital. On arrival at the ED, you give your report to the awaiting physician.

Recording Time: 12 Minutes

Respirations	26 breaths/min; normal
Pulse	Strong and regular; 130 beats/min
Skin	Warm and dry
Blood pressure	98/58 mm Hg
Oxygen saturation (SpO₂)	100% oxygen via nonrebreathing mask at 15 L/min
Pupils	PERRLA

- What are some potential complications you may encounter with a substantial burn injury such as this?
- Why is it important to assess for circumferential burns in patients with burn injuries?

other types of burns with enough advance notice. Your report and documentation should include the extent of the burns. This should include the TBSA involved, the depth of the burn, and the location. For example, you may say 10% full-thickness burns, 15% partial-thickness burns, and 25% superficial burns to the chest, abdomen, and left lower extremity. If special areas are involved (such as the genitalia, feet, hands, face, or circumferential burns), they should be specifically mentioned and documented.

Emergency Medical Care of Burns

The proper emergency care for a burn may increase a patient's chances of survival and decrease the risk or duration of long-term disability. Your first responsibility in caring for a patient with a burn is to stop the burning process and prevent additional injury.

While assessing a burned patient, check for traumatic injuries or other medical conditions that may be more immediately life threatening. Most patients who have been burned have normal vital signs and can communicate at first, which will make your assessment easier.

SKILL DRILL 28-2 presents the steps in caring for a patient with a burn.

Words of Wisdom

Remove jewelry before swelling occurs. Swelling that prevents its removal results in impaired circulation.

The goals in treating patients with burns are to stop the burning process, assess and treat breathing, support circulation (ie, supportive care for hypovolemic shock), and provide rapid transport. Because patients with burns may also have traumatic injuries, provide spinal immobilization if you suspect spinal injuries. Oxygen is mandatory for inhalation burns but is also helpful for patients with smaller burns. If the patient has signs of hypoperfusion, treat aggressively for shock, and provide rapid transport to the appropriate hospital. Cover all burns according to your local protocols. The risk of infection is extremely high and can be reduced if you cover large areas that are burned with sterile burn sheets or clean linen. Do not delay transport

of a seriously injured patient to complete non-life-saving treatments in the field, such as splinting extremity fractures. Instead, complete these types of treatments en route to the hospital.

Words of Wisdom

Separate burned fingers and toes with dry, sterile gauze to prevent them from sticking together.

Aggressive fluid resuscitation and general wound care may substantially increase chances of survival. Consider calling for paramedic backup for early definitive airway management (eg, endotracheal intubation) and pain management. Transport to the closest, most appropriate facility for definitive care.

Words of Wisdom

To help prevent hypothermia, never apply moist dressings to any patient with more than 10% of the BSA burned unless the burning process has not been stopped.

During lengthy transport times (>1 hour), medical control may order you to administer IV fluids to the burned patient based on the **Consensus formula** (formerly known as the Parkland formula). The amount of fluids administered in the first 24 hours after injury is typically 2–4 mL of lactated Ringer solution multiplied by the patient's body weight in kilograms (kg) multiplied by the percentage of TBSA burned:

$$\begin{aligned} &2\text{--}4 \text{ mL} \times \text{Patient's weight (kg)} \\ &\times \text{Percentage of BSA burned} = \text{Total fluid} \\ &\quad \text{in 24 hours} \end{aligned}$$

Thus, for a 75-kg (165-lb) patient with 45% BSA burned, the calculation is as follows, using 2 mL in the first equation and 4 mL in the second:

$$\begin{aligned} &2 \text{ (mL)} \times 75 \text{ (kg)} \times 45 \text{ (percent TBSA)} \\ &= 6,750 \text{ mL during the first 24 hours} \end{aligned}$$

or

$$\begin{aligned} &4 \text{ (mL)} \times 75 \text{ (kg)} \times 45 \text{ (percent TBSA)} \\ &= 13,500 \text{ mL during the first 24 hours} \end{aligned}$$

Skill Drill 28-2 Caring for Burns

Step 1

Follow standard precautions to help prevent infection. Because a burn destroys the patient's protective skin layer, always wear gloves and eye protection when treating a burn patient. If safe to do so, move the patient away from the burning area. If any clothing is on fire, wrap the patient in a blanket or follow specific guidelines outlined by your local fire department protocol to put out the flames, and then remove any smoldering clothing and/or jewelry.

If allowed by local protocol, immerse the area in cool, sterile water or saline solution or cover with a clean, wet, cool dressing if the wound or clothing is still hot. This not only stops the burning but also relieves pain. Prolonged immersion, however, increases the risk of infection and hypothermia. For this reason, you should not keep the affected part under water for longer than 10 minutes. Moist, sterile dressings may be used if a burn covers less than 10% of the BSA. If the burning has stopped before you arrive, do not immerse the burned part at all. As an alternative to immersion, irrigation of the burned area until the burning stops may also be used, followed by the application of a sterile dressing.

Step 2

Provide high-flow oxygen. Remember that more fire victims die of smoke inhalation than of skin burns. Respiratory distress may develop in a patient who has burns about the face or has inhaled smoke or fumes. Therefore, you should provide high-flow oxygen. Keep in mind that a patient who appears to be breathing well at first may suddenly have severe respiratory distress. Therefore, you must continue to reassess the airway for possible problems. Remember that pulse oximetry may be misleading if the patient is experiencing smoke inhalation, because of the potential for carbon monoxide poisoning.

Step 3

Rapidly estimate the burn's severity. Then, cover the burned area with a dry, sterile dressing to prevent further contamination. Sterile gauze is best if the area is not too large. You may cover larger areas with a clean, white sheet. Do not put anything else on the burned area. Never use ointments, lotions, or antiseptics of any kind (these products only increase the risk of infection and will have to be removed at the hospital), and do not intentionally break any blisters.

Step 4

Prepare for transport. Cover the stretcher with a burn sheet prior to placing the patient on it. Treat the patient for shock if necessary. Provide circulatory support, including establishing IV access using an isotonic crystalloid solution, proper positioning, and keeping the patient warm. An extensive burn can produce hypothermia (loss of body heat); prevent further heat loss by covering the patient with warm blankets.

Provide prompt transport by local protocol. Do not delay transport to perform a prolonged assessment or to apply coverings to burns in

a critically burned or injured patient. Transport to the closest, most appropriate facility in the proper mode based on the patient's condition. Provide psychological support en route.

This formula further states that one-half of this amount needs to be given during the first 8 hours and the other half needs to be given over the next 16 hours in a 24-hour period.

Continuing the example using the 2-mL amount for simplicity, the patient would receive 3,375 mL during the first 8 hours (approximately 425 mL/h).

It should be noted, however, that a burned patient with signs of inadequate perfusion (ie, shock) should receive 20-mL/kg boluses of an isotonic crystalloid as needed to maintain adequate perfusion.

Even though the Consensus formula implies that burn patients need enormous amounts of fluid, remember that you should not attempt to deliver the entire initial amount in the field. The large amounts of fluid suggested by this formula often lead providers to give more fluid than necessary prior to the patient's arrival at a burn center—a phenomenon known as fluid creep. (Interestingly, the Parkland formula was devised to limit fluid overload so that burn patients would *not* develop pulmonary edema and acute respiratory distress syndrome.) Ongoing fluid resuscitation at the hospital is based on the patient's urine output and vital signs. The original Parkland formula recommended using 4 mL/kg/percentage of TBSA as a standard for calculating fluid needs in burn patients. The Consensus formula recognizes that less than that amount is appropriate for most patients and recommends starting the calculation at one-half that total amount and then adjusting fluid requirements after the patient is in the hospital based on urine output and blood chemistry analysis.

Although burn patients will need large amounts of fluid, giving it too early or too fast can result in rapidly increasing peripheral edema that may compromise the effectiveness of airway devices and vascular access and lead to compartment syndrome. It is even more important to monitor older adults and children for fluid overload during this crucial period. In short, you must administer a lot of fluid while simultaneously monitoring the patient to ensure that you are not administering too much.

Specific Burns and Injuries

Thermal Burns

A **thermal burn** is sometimes called trauma by fire; however, heat energy can be transmitted in a variety of ways in addition to fire. Although thermal burns

are all caused by heat (as opposed to electricity, chemicals, or radiation), many different situations can cause thermal burns and pose a safety hazard to AEMTs.

Most commonly, thermal burns are caused by open flame. A **flame burn** is often a deep burn, especially if a person's clothing catches fire. The fire is fanned by running; hence, the adage “stop, drop, and roll” that is taught in schools. Wrapping the patient in a blanket or other material can also smother the flame. Flame burns may also be associated with inhalation injuries.

Hot liquids produce scald injuries. A **scald burn** is most commonly seen in children, as well as adults with disabilities, but can happen to anyone, particularly while cooking. Scald burns often cover large surface areas because liquids can spread quickly. Hot liquids can soak into clothing and continue to burn until the clothing is removed. Some hot liquids, such as oil and grease, adhere to the skin, causing particularly deep scald injuries. Approximately 375,000 scald burn injuries per year are severe enough to warrant medical attention, with 85% to 90% of those injuries occurring as the result of spilling hot food and beverages.⁷

Special Populations

Scalds and contact burns are sometimes associated with child or elder abuse. Burns in children, older people, and people with disabilities may be signs of abuse. Burns with formed shapes or unusual patterns and burns in atypical places such as the genitalia, buttocks, and thighs are often consistent with abuse.

Coming in contact with hot objects produces a **contact burn**. Ordinarily, reflexes protect a person from prolonged exposure to an extremely hot object, so contact burns are rarely deep unless the patient was prevented from drawing away from the hot object (eg, the patient was unresponsive, intoxicated, restrained, or impaired). Prolonged contact with something that is just moderately hot can eventually result in a severe burn, however. For example, a patient who has a stroke and falls against a household radiator may end up with severe burns.

A **steam burn** can produce a topical (scald) burn. Minor steam burns are common when uncovering

the plastic wrap from microwaved food. When the plastic is peeled away, hot steam escapes directly onto a person's hand. Steam (gaseous water) can also cause airway burns. Inhalation of other hot gases may cause upper airway trauma but rarely results in burns in the lower airway. Steam is unique because the minute particles of hot water can cause substantial injury to the lower airway.

A relatively rare source of thermal burns is the flash burn produced by an explosion, which may briefly expose a person to intense heat. A common source of a flash burn occurs when the patient is lighting charcoal that has been soaked in lighter fluid, generally resulting in singed hair and superficial burns of the face and arms. Lightning strikes can also cause a flash burn. These injuries are usually minor compared with the potential for trauma from whatever caused the flash.

Inhalation Burns

According to a National Fire Protection Association report, most deaths from fires are not caused directly by burns but rather result from inhalation of toxic gases, upper airway compromise, or pulmonary injury.⁸ This is generally the result of carbon monoxide or cyanide toxicity. If the patient survives the initial injury, death is usually the result of secondary infection, because the barrier of protection offered by intact skin is breached. Pathogens invade the wound shortly after the burn and may do so until the area is healed. Infection prevention is important in patients with burns.

Inhalation injuries can occur when burning takes place in enclosed spaces without ventilation. When the upper airway is exposed to excessive heat, the patient can experience rapid and serious airway compromise. The heat can be an irritant to the lungs and the airway, causing coughing, wheezing, and rapid swelling or edema of the mucosa of the upper airway tissues, often evidenced by stridor. Upper airway damage is often associated with the inhalation of superheated gases. Lower airway damage is more often associated with the inhalation of chemicals (eg, acids and aldehydes) and particulate matter. When treating a patient for inhalation injuries, you may encounter severe upper airway swelling, requiring intervention immediately after a severe burn, although this problem may not manifest itself until transport. You should consider requesting

paramedic backup if the patient has signs or symptoms of edema such as stridor, a hoarse voice, singed nasal hairs, singed facial hairs, burns of the face, or carbon particles in the sputum. Application of cool mist, aerosol therapy, or humidified oxygen may help reduce some minor edema. Saline placed in a nebulizer can also provide humidified air.

Signs and symptoms of lower airway injury are usually seen later than those of the upper airway. The patient may appear unharmed only to die several hours later of pulmonary complications. It is important to maintain a high index of suspicion for any patient exposed to a burning environment.

Prehospital care of a patient with an inhalation injury is the same as for any other burned patient, with specific attention to the airway. Early recognition and treatment of a patient with an inhalation injury are key to survival. Consider calling for paramedic backup for early definitive airway treatment for a patient with an altered mental status, before edema makes such treatment virtually impossible. Prompt transport to the closest, most appropriate facility is imperative. This may include transport to a facility with access to a hyperbaric chamber for patients with suspected carbon monoxide poisoning. Patients who are hypoxic may be anxious or agitated. Provide psychological support en route.

Carbon Monoxide Intoxication

Toxins in the smoke greatly increase the risk of morbidity and mortality. As the fire uses up the oxygen in an enclosed space, the patient is left to breathe toxins such as carbon monoxide. Because carbon monoxide will bind to hemoglobin 200 times more readily than oxygen, signs of hypoxia can develop rapidly in the patient. Permanent damage to organs, including the brain, may occur if the patient is not rescued and treated promptly.

Carbon monoxide intoxication should be considered whenever a group of people in the same place all report a headache or nausea (a malfunctioning furnace or car exhaust being sucked into the air-handling system can cause carbon monoxide intoxication in groups of people). Similarly, you should be suspicious when people complain of feeling sick at home but not when they go to work or school.

Patients with severe carbon monoxide intoxication usually have an oxygen saturation level that is normal or better. For this reason, you should be

suspicious of pulse oximeter readings when you are dealing with a patient who is suspected to have carbon monoxide poisoning. Devices that can measure a patient's carbon monoxide level are sometimes used in prehospital care; they allow you to find and treat low-level carbon monoxide intoxication far more readily than any other method available in the prehospital environment.

Hydrogen Cyanide Poisoning

The gaseous form of cyanide is hydrogen cyanide. Hydrogen cyanide is present in the smoke of certain substances when burned, such as wood and certain plastics. It is also present in vehicle exhaust. Hydrogen cyanide is colorless and has the smell of bitter almonds; however, it can be difficult to detect at the scene of a fire. Prehospital diagnosis of hydrogen cyanide poisoning is difficult because laboratory studies are necessary. Signs and symptoms involve the central nervous, respiratory, and cardiovascular systems of the body and include faintness, anxiety, abnormal vital signs, headache, seizures, paralysis, and coma.

Chemical Burns

A chemical burn can occur whenever a toxic substance contacts the body. Strong acids or strong alkalis (bases) cause most chemical burns. Both acids and alkalis are defined as caustic and cause substantial tissue damage on contact. The eyes are particularly vulnerable to chemical burns (**FIGURE 28-20**). Sometimes simply the fumes of strong chemicals can cause burns, especially to the respiratory tract.

FIGURE 28-20 The eyes are particularly vulnerable to chemical burns.

© Jones & Bartlett Learning.

To prevent exposure to hazardous materials, you must wear the appropriate personal protective equipment (such as gloves and eye protection) whenever you are caring for a patient with a chemical burn. Be particularly careful not to get any chemical, dry or liquid, on yourself or on your uniform; consider wearing a protective gown when this is a possibility. Remember that exposure risk is also present when you are cleaning up after the call. In cases of severe chemical burns or exposure, consider mobilization of a hazardous materials (hazmat) team, if appropriate.

Safety

Some chemicals react violently with water, which obviously precludes irrigation. Such chemicals are usually powders, so it is reasonable to brush off as much dry powder as possible. You should understand the chemical you are dealing with and the preferred method for its removal prior to initiating irrigation with water.

The severity of a chemical burn is related to several factors, including the following:

- The pH level of the agent
- The concentration of the agent
- The length of time the patient was exposed to the agent
- The volume of the agent
- The physical form of the agent

Ingestion of solid agents, such as pills, results in a longer exposure time as the offending substance travels through the digestive system. In addition, concentrated forms of some acids and alkalis generate substantial heat when diluted, resulting in thermal and caustic injury. Because industrial accidents are the most frequent types of chemical exposures, consider the MOI as well.

Treatment for chemical burns can be specific to the chemical agent. When the incident occurred in an industrial setting, ask for copies of material safety data sheets from the employer. If available, read all labels for the chemical agent. You may also contact poison control for assistance if you are not sure of how to respond to an incident involving a specific chemical. Do not risk exposure while attempting to gather information on the chemical.

FIGURE 28-21 Brush off dry chemicals before you flush the burned area with water.

© American Academy of Orthopaedic Surgeons.

Words of Wisdom

Many industrial sites have experts available on scene to assist with exposures.

To stop the burning process, remove any chemical from the patient. A dry chemical that is activated by contact with water may damage the skin more when it is wet than when it is dry. Therefore, always brush dry chemicals off the skin and clothing before flushing the patient with water (**FIGURE 28-21**). Remove the patient's clothing, including shoes, stockings, and gloves, and any jewelry or eyeglasses, because there may be small amounts of chemicals in the creases. Chemical burns are evaluated in the same manner as thermal burns when classifying depth or TBSA.

After brushing off the chemical, begin to flush the burned area with large amounts of water (**FIGURE 28-22**), taking care not to contaminate uninjured areas or make the patient hypothermic. This should be integrated with your primary survey of the patient. Never direct a forceful stream of water from a hose at the patient; the extreme water pressure may mechanically injure the burned skin. Continue flooding the area with copious amounts of water for 15 to 20 minutes after the patient says the burning pain has stopped. Continue flushing the contaminated area on the way to the hospital. Do not use any antidote or neutralizing agent. More damage may be

FIGURE 28-22 Flush the burned area with large amounts of water for 15 to 20 minutes after the patient says that the burning pain has stopped. Avoid contaminating uninjured areas.

© Jones & Bartlett Learning.

caused by the chemical reaction of the antidote or neutralizing agent with the contaminant. Treat all chemical exposures according to local protocols.

Words of Wisdom

For a patient who has had a chemical exposure, *never* pull the patient's shirt over the head. This could result in chemicals being rubbed into the mouth, nose, or eyes.

Several types of chemical burns require special management techniques:

- **Dry lime.** In alkali burns caused by dry lime, combination with water will produce a highly corrosive substance. For that reason, when a patient has been in contact with dry lime, *first* remove the patient's clothing and *brush* as much lime as you can from the skin (wear gloves!). *Then* start flushing copiously with a garden hose or shower. Your intention is to completely overwhelm any damaging chemical reaction with a deluge of water.

- **Sodium metals.** Sodium metals produce considerable heat when mixed with water and may explode. Cover this type of burn with oil, which will stop the reaction by preventing the sodium from coming in contact with the atmosphere.
- **Hydrofluoric (HF) acid.** HF acid is used in drain cleaners in the home and for etching glass and plastic in industrial settings. Burns caused by HF acid that exceed 3% to 5% of TBSA can be fatal. The patient will complain bitterly of pain (caused by the HF acid sucking calcium out of the body), and the pain will not improve even with continuous flushing; a sign that the process of tissue destruction is ongoing. Calcium gluconate gel is the preferred treatment for HF acid burns.
- **Gasoline or diesel fuel.** Because we come in contact with these chemicals almost every day, and they are present at almost all vehicle crashes, it is easy to forget the multitude of potential problems that may be caused by gasoline, kerosene, and other hydrocarbons. Prolonged contact may produce a chemical injury to the skin. This condition is managed like contact with any other chemical irritant, with the fuel being washed off as soon as possible. Most hydrocarbons are more effectively removed with a soap solution than with water alone. Hydrocarbons also stimulate gamma-aminobutyric acid receptors and can cause sleepiness and even coma. Many hydrocarbons can also cause a fire or explosion under certain circumstances.
- **Hot tar.** Burns caused by hot tar are, strictly speaking, thermal burns, not chemical burns, although they tend to be classified with chemical burns. The most important step in the pre-hospital phase is to immerse the affected area in cold water to dissipate the heat from the tar and speed up the hardening process. After the tar has cooled, it will not do further damage, and there is no need to try to remove it in the field.

When treating chemical burns, give particular attention to the eyes. Caustic chemicals introduced into the eyes will produce burns similar to those of thermal burns. If not removed quickly, the burning process will continue through the various layers of the eye. Chemical injuries to the eyes may be the result of acids, alkalis, mace, pepper spray, or other irritants.

If the patient's eye has been burned, hold the eyelid open (without applying pressure over the globe of the eye) while flooding the eye with a gentle stream of water (**FIGURE 28-23**). Flush the eyes from the inside corners to the outside to prevent cross contamination. If only one eye has been affected, turn the patient's head to that side and flush. If both eyes are affected, consider hooking up a nasal cannula to a bag of saline to flush both eyes simultaneously. The prongs can be placed on the bridge of the nose to flush from the inside corners of the eyes to the outside corners. Be careful not to touch the prongs to the eye or surrounding tissue. Continue flushing the contaminated area on the way to the hospital.

Irrigate the eye for at least 5 minutes. If an alkali or a strong acid caused the burn, you should irrigate the eye for 20 minutes. After you have completed irrigation, apply a clean, dry dressing to cover the eye, and transport the patient promptly to the hospital for further care. If the irrigation can be carried out satisfactorily in the ambulance, it should be done during transport to save time.

Electrical Burns

Electrocution results in an average of 1,000 deaths and 30,000 injuries each year.⁹ Electrical burns may be the result of contact with high- or low-voltage electricity. High-voltage burns may occur when utility workers make direct contact with power lines. Ordinary household current is powerful enough to cause severe burns as well as cardiac dysrhythmias.

For electricity to flow, there must be a complete circuit between the electrical source and the

FIGURE 28-23 Flood the affected eye with a gentle stream of water. Holding the eyelids open is a challenging task because the patient's reflex is to keep the eye shut. Take care to prevent any of the chemical from getting into the other eye during flushing.

ground. Any substance that prevents this circuit from being completed, such as rubber, is called an insulator. Any substance that allows a current to flow through it is called a conductor. The human body, which is primarily water, is a good conductor. Thus, electrical burns occur when the body, or a part of it, completes a circuit connecting a power source to the ground (**FIGURE 28-24**).

Heat is generated by the flow of electrical current through body tissues, resulting in direct thermal injury. Vascular injuries, renal injuries, and compartment syndrome may also result.

An electrical burn will result in two burn injuries: one where the electricity entered the body (an entrance wound) and another where it exited (an exit wound). The entrance wound may be quite small (**FIGURE 28-25A**), but the exit wound can be extensive and deep (**FIGURE 28-25B**). Always look for entrance *and* exit wounds.

There are two dangers specifically associated with electrical burns. First, there may be a large amount of deep tissue injury. Electrical burns are always more severe than the external signs indicate. The patient may have only a small burn to the skin but massive damage to the deeper tissues, organs, and the nervous system (**FIGURE 28-26**). The force of the electrical energy can also cause fractures or joint dislocations. Second, the patient may go into cardiac or respiratory arrest from the electric shock. When the path of electricity travels from hand to hand, it generally flows through the heart, disrupting normal function of the cardiac conduction system.

Your safety is particularly important when you are called to the scene of an emergency involving electricity. Obviously, coming into direct contact with power lines can fatally injure you, but it is

important to remember that touching a patient who is still in contact with a live power line or any other electrical source can be fatal to you as well. For this reason, you must never attempt to remove someone from an electrical source unless you are specifically trained to do so. Likewise, never move a downed power line unless you have the special training and

A

B

FIGURE 28-25 Electrical burns, like gunshot wounds, have entrance and exit wounds. **A.** An entrance wound is often quite small. **B.** The exit wound can be extensive and deep.

FIGURE 28-24 The human body is a good conductor of electricity. An electrical burn usually occurs when the body, acting as a conductor, completes a circuit.

© Jones & Bartlett Learning.

FIGURE 28-26 External signs of an electrical burn may be deceiving. The entrance wound may be a small burn, but the damage to deeper tissue may be massive.

© Jones & Bartlett Learning.

equipment necessary for the job or unless you are absolutely certain that the line is not live. Notify your dispatcher to send the power company for assistance. Before even approaching someone who may still be in contact with a power line or an electrical appliance, make certain that the power is turned off. Always assume that any downed power line is live.

Safety

Do not try to remove someone from an electrical source or move a downed power line unless you are specifically trained and equipped to do so. Before approaching someone who may still be in contact with a power line or electrical appliance, ensure that all power is turned off.

Not all electrical injuries are the same. Determine the voltage and type of current if possible. Identify whether the injury was brief or sustained and an approximate time of contact. Note if the patient is wet or near water; this can influence the amount of energy transferred. Also ask about any loss of consciousness and any preexisting medical conditions that may exacerbate the problem and hinder effective resuscitation.

As with thermal burns, consider early definitive care of the airway if the patient is unable to maintain the airway. Consider paramedic backup for early intubation of patients unable to maintain their own airway.

When assessing circulation, look for signs of hypoperfusion and assess the heart rate, specifically for regularity to detect potentially life-threatening dysrhythmias. As mentioned, cardiac dysrhythmias are common with electrical burns. If indicated, begin CPR and apply an automated external defibrillator. Although CPR may need to be quite prolonged in electrical burn cases, it has a high success rate if started promptly. Be prepared to defibrillate if necessary. If neither CPR nor defibrillation is indicated, give high-flow supplemental oxygen, and monitor the patient closely for respiratory and cardiac arrest. Establish IV access using an isotonic crystalloid solution, and administer a bolus of 250 mL, increasing up to four doses as needed, or a dose based on local protocols. This will help to maintain an adequate urine output of 1 mL/kg per hour and adequate renal perfusion.

Provide prompt transport to the closest, most appropriate facility; all electrical burns are potentially severe injuries that require further treatment in the hospital. Remember that very old and very young patients, as well as patients with preexisting conditions, are at greater risk for severe morbidity and mortality.

Taser Effects

Devices such as a conducted electrical weapon (CEW) or Taser incapacitate people via electromuscular disruption. Although they are intended to offer law enforcement personnel a nonlethal option for controlling violent people, their use can create injuries that require emergency medical care. If discharged from a distance, two small darts (electrodes) that puncture the patient's skin are deployed from these weapons. Taser darts can be seen as small impaled objects, with a fishhook-like barb on the end. Although the resultant injury is typically minor, reports have cited hits to sensitive areas such as the eyes, major vessels, face, and genitalia. Even innocuous dart placement could potentially result in soft-tissue injury, bleeding, or infection, and dart removal should be done with care and while complying with the appropriate standard precautions. Always follow local protocols for removal of taser darts.

Several reports of deaths in people who have been shocked with a Taser have made the use of these devices controversial.^{10,11} In addition, cases exist in which people who have been covered with alcohol-based pepper spray have subsequently caught fire when an electroshock device was applied.¹² (Water-based pepper spray is typically used in the United States.) Manufacturers now recommend that such devices not be used in potentially flammable environments such as gas stations or near illicit methamphetamine-manufacturing operations.

Words of Wisdom

Lightning injuries are another type of electrical injury. In patients who sustained lightning injury, it is important to remember that reverse triage applies: priority for treatment goes to patients in cardiac arrest from lightning strike because they have a good chance of successful resuscitation, even when they appear to be beyond help. Provide aggressive, continued, high-quality CPR, and apply an automated external defibrillator as soon as possible. Lightning injuries are covered in Chapter 34, *Environmental Injuries*.

Radiation Burns

Radiation exposure has become more than a theoretical issue as use of radioactive materials increases in industry and medicine, and you must understand it to function effectively in the prehospital arena. Between 1944 and 2010, there were more than 400 radiation accidents worldwide involving substantial radiation exposure to more than 3,000 people.¹³ More recent events in Japan (the earthquake-triggered tsunami that damaged the Fukushima Daiichi Nuclear Power Plant in March 2011) highlight that radiation accidents continue to be a threat. Other potential threats include incidents related to the use and transportation of radioactive isotopes and intentionally released radioactivity in terrorist attacks. To be effective in treating patients with radiation exposure, you must first suspect radiation and attempt to determine whether ongoing exposure exists. Increasingly, special response units are equipped with pager-sized radiation detectors, or such detection may be provided by other public safety services.

Ionizing radiation is made up of subatomic particles that contain an excess amount of energy that is emitted into the atmosphere in certain circumstances, creating radiation. These charged particles

(ions) can cause damage to molecules, cells, and tissues. Any amount of ionizing radiation will produce some damage.

The three most common types of ionizing radiation are alpha particles, beta particles, and gamma. Inhalation, ingestion, and direct exposure are the three basic pathways by which people are exposed. The amount and duration of exposure affect the severity or type of health effect.

Acute exposure to radiation may result in burns and radiation sickness or radiation poisoning. Radiation sickness can cause premature aging or even death. If the dose is fatal, death usually occurs within 2 months. The symptoms of radiation sickness include nausea, weakness, hair loss, skin burns, and diminished organ function.

Radiation burns require special rescue techniques beyond the initial training of AEMTs. If not properly trained, maintain a safe distance and wait for the hazmat team to decontaminate the patient before initiating care. Follow local protocols. Establish IV access, and give fluid based on patient presentation. If there are signs of shock, give a 250-mL bolus of an isotonic crystalloid solution and reassess.

YOU are the Provider SUMMARY

1. How do you calculate the percentage of burned area?

Burns are calculated by using the rule of nines or the rule of palms. The rule of nines divides the body into sections, each of which is approximately 9% of the TBSA. The rule of palms is a quick way to estimate the surface area that has been burned. To use the rule of palms, compare the burned area with the size of the patient's palm, which is roughly equivalent to 1% of the patient's TBSA. This calculation is helpful when the burn covers less than 10% of TBSA or is irregularly shaped.

2. What classification of burns does this patient have?

This patient's burn falls into the classification of severe burns based on the patient's full-thickness burns, including the full-thickness burns involving the genitalia. Also, the patient's burns cover more than 10% of his TBSA.

3. What immediate treatment is required for this patient?

Immediate treatment for this patient includes stopping the burning process by removing any

still-burning materials and assessing the airway for potential burns. Because burns can be extremely painful, a paramedic intercept should be requested for narcotic pain management.

4. Because this patient is complaining of pain, should you apply moist dressings in an attempt to cool the burned area?

Moist dressings should be avoided in this patient because of the large percentage of burned area involved. Application of moist dressings may precipitate hypothermia. Instead, this patient should have his burns covered with dry, sterile dressings to reduce the introduction of bacteria into the burned area.

5. Should you attempt IV access through the burned area?

IV access is crucial in a burned patient. Attempt IV access in an unburned area first. If you are unable to locate a vein in an unburned area, it is acceptable, although not optimal, to obtain access through a burned area. Remember, there is always the option of gaining intraosseous access if there is an unburned area available.

YOU are the Provider SUMMARY *continued***6. How would you calculate the amount of fluid the patient requires?**

Fluid replacement in a burned patient is calculated by using the Consensus formula. This formula is obtained by taking the patient's weight in kilograms multiplied by 2–4 mL multiplied by the TBSA burned. In this case, using 2 mL, it is $2 \text{ mL} \times 80 \text{ kg} \times 55\%$, which equals 8,800 mL of fluid that needs to be administered over the first 24 hours, with one-half that amount (4,400 mL) needing to be infused over the first 8 hours.

7. What are some potential complications you may encounter with a substantial burn injury such as this?

Some potential complications you may encounter would be a potential airway obstruction from

swelling and edema, shock resulting from hypovolemia, hypothermia, and compartment syndrome.

8. Why is it important to assess for circumferential burns in patients with burn injuries?

A circumferential burn may result in compartment syndrome, in which tissues beneath the eschar are unable to stretch, resulting in compression and decreased or absent circulation. If the burn is around the thorax, tidal volume and chest excursion may be drastically reduced by the eschar formation, resulting in ventilatory insufficiency. A circumferential eschar around an extremity may require an escharotomy—a surgical incision to relieve the pressure and restore circulation—after the patient arrives at the ED.

EMS Patient Care Report (PCR)

Date: 10-6-21	Incident No.: 4067521733	Nature of Call: Explosion	Location: Lake Bronson		
Dispatched: 1602	En Route: 1604	At Scene: 1614	Transport: 1622	At Hospital: 1644	In Service: 1713

Patient Information

Age: 19
Sex: M
Weight (in kg [lb]): 80 kg (178 lb)

Allergies: None
Medications: None
Past Medical History: None
Chief Complaint: Burns/pain

Vital Signs

Time: 1615	BP: Not obtained	Pulse: Not obtained	Respirations: 28	Spo₂: Not obtained
Time: 1622	BP: 102/64	Pulse: 137	Respirations: 26	Spo₂: 100% on 15 L/min
Time: 1627	BP: 98/58	Pulse: 130	Respirations: 26	Spo₂: 100% on 15 L/min

EMS Treatment (circle all that apply)

Oxygen @ 15 L/min via (circle one): NC (NRM) Bag-mask device		Assisted Ventilation	Airway Adjunct	CPR
Defibrillation	Bleeding Control	Bandaging	Splinting	Other:

Narrative

EMS dispatched to Lake Bronson for a reported explosion. On arrival, patient found lying on ground in severe pain. Bystanders state that patient was pouring gasoline in a barbeque when it flashed. Patient is AO×4; ABCs intact. Smoldering clothes noted on chest, removed. Full-thickness burns to chest, bilateral arms and legs, and groin. Estimated 55% total BSA burned. Paramedic intercept requested but unavailable. Patient denies any other injuries but complains of 10/10 pain. Placed patient on stretcher, secured, emergency transport to Kalispell Regional Medical Center (KRMC). En route: Bilateral 18-gauge IVs established, 500-mL LR bolus to each IV. Consensus formula calculated at 8.8 L over 24 hours. Covered patient with dry, sterile dressings. 100% oxygen at 15 L/min applied via nonbreathing mask. On arrival at KRMC, care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- The soft tissues of the body can be injured through a variety of mechanisms such as blunt trauma, penetrating trauma, and burn injuries.
- Death as a result of soft-tissue injury is often related to hemorrhage or infection.
- The skin has two principal layers: the tough outer layer, called the epidermis, and the inner layer, called the dermis, which contains the hair follicles, sweat glands, and sebaceous glands.
- The functions of the skin are to keep bacteria out and water in, to report to the brain on the environment and sensations, and to regulate body temperature.
- Skin tension lines (patterns of tautness in the skin) affect wound healing.
- Concerns during wound healing include infection, gangrene, tetanus, and necrotizing fasciitis.
- Soft-tissue injuries can be subdivided into three types:
 - Closed injuries (Soft-tissue damage occurs beneath the skin or mucous membrane but the surface remains intact.)
 - Open injuries (There is a break in the surface of the skin or the mucous membrane, exposing deeper tissue to potential contamination.)
 - Burns (The soft tissue receives more energy than it can absorb without injury; the source of this energy can be thermal, frictional heat, toxic chemicals, electricity, or nuclear radiation.)
- Closed injuries include contusions, hematomas, and crushing injuries.
- Open injuries produce more extensive bleeding than closed injuries and may become infected.
- Types of open injuries include abrasions, lacerations, avulsions, amputations, bite wounds, penetrating wounds, and blast injuries.
- The assessment of an open injury is generally easier than the assessment of a closed injury because you can see the injury.
- Because skin injuries typically result in a risk of exposure to blood and other body fluids, scene size-up should include infection control procedures and standard precautions.
- Life-threatening conditions must be managed first; bleeding may not always be the most life-threatening condition. However, substantial bleeding is an immediate life threat and must be controlled quickly using appropriate methods.
- Be alert for shock in all patients with soft-tissue injury, but especially patients with closed injuries. Assess the pulse and skin to determine how aggressively you need to treat for shock.
- Soft-tissue injuries can severely compromise the airway. Immediately correct anything that interferes with airway patency.
- After the primary survey, you must make a priority decision to rapidly package and transport or to stabilize and treat on scene.
- Closed soft-tissue injuries are characterized by a history of blunt trauma, pain at the site of injury, swelling beneath the skin, and discoloration. Treat a closed soft-tissue injury by applying the mnemonic RICES: *Rest, Ice, Compression, Elevation, and Splinting*.
- Dressings and bandages are designed to control bleeding, protect the wound from further damage, and prevent further contamination and infection.
- In treating open injuries, first control bleeding. Use a dry, sterile dressing, covered by a roller bandage, a second pressure dressing (if necessary), and a splint. Do not try to clean out an open wound.
- To treat avulsions, replace the avulsed flap in its original position. If an avulsion is complete, wrap the separated tissue in sterile gauze, and take it with you to the ED. Never remove

an avulsion skin flap, regardless of the size of the flap.

- Control bleeding from amputations with pressure dressings or other methods as needed. With partial amputations, make sure to immobilize the part with bulky compression dressings and a splint to prevent further injury. Never detach partial amputations. For complete amputations, wrap the part in a sterile dressing, place it in a plastic bag, and follow your local protocols.
- Animal and human bites can result in serious infection and must be treated by a physician. Dogs and cats can carry rabies, an acute, potentially fatal viral infection present in their saliva. By law, all animal bites must be reported to the appropriate authority.
- Penetrating wounds may have entrance and exit wounds; for example, if the cause was a gun. Find out the caliber of the gun, if possible.
- If internal organs are protruding through an open wound, do not touch or move the exposed organs. Cover the wound with sterile gauze compresses moistened with sterile saline solution, and secure with an occlusive dressing.
- In the case of an impaled object, do not remove it. Stabilize it with a bulky dressing, and protect it from being moved during transport.
- An open neck injury can be life threatening. Bleeding control is crucial. Secure an occlusive dressing over the wound, and apply manual pressure.
- Although it is not always possible to use the sterile technique, you should make every effort to avoid further wound contamination. Irrigate open wounds with normal saline or sterile water to flush out contaminants.
- Burns are one of the most serious and painful of soft-tissue injuries. They can occur from heat (thermal), chemicals, electricity, and radiation.
- Burns are classified primarily by the depth and extent of the burn and the body area involved; they are superficial, partial-thickness, or full-thickness burns. The rule of nines and rule of palms can be used to estimate the surface area that has been burned.
- Although a burn may be the patient's most obvious injury, you should always perform a complete assessment to determine whether there are other, more serious injuries.
- Special emergency treatment considerations for burns include removing the patient from the burning area; removing jewelry and constrictive clothing; estimating the size of the burned area; covering it with a dry, sterile dressing; covering the stretcher with a burn sheet prior to placing the patient on it; and covering the patient with a clean blanket to prevent hypothermia.
- Be alert to signs and symptoms of inhalation injury such as difficulty breathing, stridor, and/or wheezing. Follow local protocols regarding cooling measures.
- Treat the patient for shock if necessary. Provide circulatory support, including establishing IV access and administering an isotonic crystalloid solution according to the Consensus formula, and proper positioning.
- There are several types of burns. A thermal burn is caused by heat, commonly an open flame. Types of thermal burns include scald burns, contact burns, steam burns, and flash burns. Follow the standard assessment and treatment process for burns.
- Inhalation burns can cause rapid and serious airway compromise, resulting in coughing, wheezing, and rapid swelling or edema of the mucosa of the upper airway tissues, often evidenced by stridor. Consider requesting paramedic backup if the patient has stridor, a hoarse voice, singed nasal hairs, singed facial hairs, burns of the face, or carbon particles in the sputum.
- A chemical burn can occur whenever a toxic substance contacts the body. You may need to wait for hazardous materials personnel before treating the patient. Wear protective equipment. A dry chemical must be brushed off the skin and clothing before flushing the patient with water. Remove the patient's clothing before flushing with water. Treat chemical burns to the eyes by flushing with copious amounts of water or a sterile saline irrigation solution. Avoid contaminating areas

that were not yet exposed to the chemical, such as the other eye.

- Electrical burns can cause thermal injury, vascular injury, renal injury, compartment syndrome, and possible cardiac arrest. There will be an entrance and an exit wound. Do not touch power lines. Never attempt to remove someone from an electrical source unless you are specifically trained to do so. Consider paramedic backup for early intubation.

- Radiation injuries are caused by ionizing radiation emitted by certain sources. Acute exposure to radiation may result in burns and radiation sickness or radiation poisoning. Symptoms of radiation sickness include nausea, weakness, hair loss, skin burns, and/or diminished organ function. Radiation burns require special rescue techniques beyond the initial training of AEMTs.

Vital Vocabulary

abrasion The loss or damage of the superficial layer of skin as a result of a body part rubbing or scraping across a rough or hard surface.

air embolism The presence of air in the venous circulation, which forms a gas bubble that can block the outflow of blood from the right ventricle to the lung; can lead to cardiac arrest, shock, or other life-threatening complications.

amputation An injury in which part of the body is completely severed; complete avulsion.

avulsion An injury in which soft tissue is torn completely loose or is hanging as a flap.

burns Injuries in which the soft tissue receives more energy than it can absorb without injury, from thermal heat, frictional heat, toxic chemicals, electricity, or nuclear radiation.

closed injury An injury in which damage occurs beneath the skin or mucous membrane but the surface remains intact.

compartment syndrome An elevation of pressure within the fascial compartment, characterized by extreme pain, decreased pain sensation, pain on stretching of affected muscles, and decreased power; most frequently seen in fractures below the elbow or knee in children.

Consensus formula A formula that recommends giving 2 to 4 mL of lactated Ringer solution for each kilogram of body weight, multiplied by the percentage of total body surface area burned during the first 24 hours following the burn; one-half of the volume is given in the first 8 hours and the other half in the next 16 hours; sometimes used to calculate fluid needs during lengthy

transport times; formerly called the Parkland formula.

contact burn A burn produced by touching a hot object.

contamination The presence of infectious organisms (pathogens) or foreign bodies such as dirt, gravel, or metal in a wound.

contusion A bruise without a break in the skin; ecchymosis.

crush syndrome Significant metabolic derangement that develops when crushed extremities or body parts remain trapped for prolonged periods; it can lead to renal failure and death.

dermis The inner layer of the skin, containing hair follicles, sweat glands, sebaceous glands, nerve endings, and blood vessels.

ecchymosis Bruising or discoloration associated with bleeding within or under the skin.

epidermis The outer layer of skin, which is made up of cells that are sealed together to form a watertight protective covering for the body.

eschar The thick, coagulated crust or slough of leathery skin that develops following a burn.

evisceration The displacement of organs outside of the body.

fasciitis Inflammation of the fascia.

flame burn A thermal burn caused by flames touching the skin.

full-thickness burns The burns that affect all skin layers and may affect the subcutaneous layers, muscle, bone, and internal organs, leaving the area dry, leathery, and white, dark brown, or

charred (eschar); formerly called a third-degree burn.

gangrene An infection commonly caused by *Clostridium perfringens*. The result is tissue destruction and gas production that may result in death.

hematoma Blood collected within the body's tissues or in a body cavity.

inhalation injury An injury to the airway as a result of breathing smoke and toxic chemicals into the lungs and airway.

laceration A smooth or jagged open wound.

mucous membranes The lining of body cavities and passages that communicate directly or indirectly with the environment outside the body.

necrotizing fasciitis Death of tissue from bacterial infection, caused by more than one infecting organism—most commonly, *Staphylococcus aureus* and hemolytic streptococci; this condition has a high mortality rate.

occlusive dressing A dressing made of petroleum (Vaseline) gauze, aluminum foil, or plastic that prevents air and liquids from entering or exiting a wound.

open injury An injury in which there is a break in the surface of the skin or the mucous membrane, exposing deeper tissue to potential contamination.

partial-thickness burns The burns affecting the epidermis and some portion of the dermis but not the subcutaneous tissue, characterized by blisters and skin that is white to red, moist, and mottled; formerly called a second-degree burn.

penetrating wound An injury that penetrates the skin, resulting from a sharp, pointed object or a blunt object traveling at sufficient speed, such as a knife or a bullet.

rabid Describes an animal that is infected with rabies.

rule of nines A system that assigns percentages to sections of the body, allowing calculation of

the amount of skin surface involved in the burn area.

rule of palms A system that estimates total body surface area burned by comparing the affected area with the size of the patient's palm, which is roughly equivalent to 1% of the patient's total body surface area.

scald burn A burn produced by hot liquids or steam.

steam burn A burn that has been caused by direct exposure to hot steam exhaust, as from a broken pipe.

superficial burns The burns affecting only the epidermis, characterized by skin that is red but not blistered or burned through; formerly called a first-degree burn.

tension lines The pattern of tautness of the skin, which is arranged over body structures and affects how well wounds heal.

tetanus A disease caused by the spore-forming bacterium *Clostridium tetani* that enters the body through a puncture wound contaminated with animal feces, street dust, or soil or that can enter through contaminated street drugs.

thermal burn A burn that results from heat, usually fire.

zone of coagulation The reddened area surrounding the leathery and sometimes charred tissue that has sustained a full-thickness burn; point of maximum damage.

zone of hyperemia In a thermal burn, the area that is least affected by the burn injury; an area of increased blood flow where the body is attempting to repair injured but otherwise viable tissue.

zone of stasis The peripheral area surrounding the zone of coagulation that has decreased blood flow and inflammation; it can undergo necrosis within 24 to 48 hours after the injury, particularly if perfusion is compromised because of burn shock.

Chapter 29

Face and Neck Injuries

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Diseases of the Eyes, Ears, Nose, and Throat

Recognition and management of

- Nosebleed (pp 1381–1382)

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Head, Facial, Neck, and Spine Trauma

Recognition and management of

- Life threats (pp 1364–1366)
 - Spine trauma (Chapter 30, *Head and Spine Injuries*)
- Pathophysiology, assessment, and management of
- Penetrating neck trauma (p 1386)
 - Laryngotracheal injuries (pp 1386–1388)
 - Spine trauma (Chapter 30, *Head and Spine Injuries*)
 - Facial fractures (pp 1361–1363)
 - Skull fractures (Chapter 30, *Head and Spine Injuries*)
 - Foreign bodies in the eyes (pp 1372–1374)
 - Dental trauma (pp 1384–1385)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the head, face, and neck, including the major structures and specific landmarks that advanced emergency medical technicians must know. (pp 1357–1359)
2. Describe the factors that may cause the obstruction of the upper airway following a facial injury. (pp 1359–1360)
3. Discuss the causes and the patient care considerations related to each of the following types of facial injuries: soft-tissue injuries, nasal fractures, mandibular fractures, Le Fort fractures, orbital fractures, and zygomatic fractures. (pp 1360–1363)
4. Explain the patient assessment and management process of providing emergency medical care to the patient who has sustained facial and neck injuries. (pp 1364–1370)
5. List the steps in the emergency medical care of the patient with soft-tissue wounds of the face and neck. (pp 1370–1371)
6. List the steps in the emergency medical care of the patient with an eye injury based on the following scenarios: foreign object, impaled object, burns, lacerations, blunt trauma, closed head injuries, and blast injuries. (pp 1371–1380)
7. Describe the three different causes of burn injuries to the eye and the patient management

considerations related to each cause.
(pp 1374–1376)

8. List the steps in the emergency medical care of the patient with an injury of the nose.
(pp 1381–1382)
9. List the steps in the emergency medical care of the patient with one of the following injuries of the ear: lacerations, avulsions, foreign body insertions, and perforation of the tympanic membrane. (pp 1382–1383)
10. List the steps in the emergency medical care of the patient with a facial fracture.
(pp 1383–1384)
11. List the steps in the emergency medical care of the patient with dental and cheek injuries, including management of oropharyngeal bleeding, impaled objects, and avulsed teeth.
(pp 1384–1385)
12. List the steps in the emergency medical care of the patient with an upper airway injury caused by blunt trauma. (p 1385)
13. List the steps in the emergency medical care of the patient with a penetrating injury to the neck, including management of regular and life-threatening bleeding and impaled objects.
(p 1386)
14. List the steps in the emergency medical care of the patient with laryngeal injuries, including both open and occult injuries. (pp 1386–1388)
15. List the steps in the emergency medical care of the patient with muscular injuries of the neck, including both sprains and strains. (p 1388)

SKILLS OBJECTIVES

1. Demonstrate the care of a patient who has a penetrating eye injury. (pp 1377–1378)
2. Demonstrate the removal of a foreign object from under a patient's upper eyelid. (p 1373, Skill Drill 29-1)
3. Demonstrate the stabilization of a foreign object that has been impaled in a patient's eye.
(p 1374, Skill Drill 29-2)
4. Demonstrate irrigation of a patient's eye using a nasal cannula, bottle, or basin. (p 1376)
5. Demonstrate how to control bleeding from a neck injury. (p 1387, Skill Drill 29-3)

Introduction

Because the face and neck are among the most exposed regions of the body, they are frequently subjected to traumatic forces ranging from simple falls to assaults to direct blunt forces sustained in motor vehicle crashes (MVCs). Whereas other regions of the body are often covered with clothing and protective equipment, the face and neck generally do not have this same level of protection; therefore, these areas are particularly vulnerable to injury. In many cases, the injuries in this region will be some of the first you see when you arrive at the patient's side. Moreover, these injuries can be some of the most graphic. Be careful not to focus solely on these distracting injuries to avoid increasing the risk of missing other life threats.

Soft-tissue injuries and fractures to the bones of the face are common, although they vary greatly in severity. Some are potentially life threatening, and many leave disfiguring scars if not treated properly. Penetrating trauma to the neck may cause severe bleeding. An open injury may allow an air

embolism to enter the circulatory system. If a hematoma forms in this area, then it may stop or slow blood flow to the brain, causing a stroke. Nevertheless, with appropriate prehospital and hospital care, even a patient with a seemingly devastating injury can have a surprisingly good outcome.

As an advanced emergency medical technician (AEMT), your objectives when treating a patient with face and neck injuries include preventing further injury (particularly to the cervical spine), managing any acute airway problems, and controlling bleeding. This chapter will first review the anatomy of the head and neck. Next, it will examine the factors that can produce upper airway obstruction. The chapter will then cover emergency medical care of soft-tissue wounds of the face, nose, and ear; facial fractures; penetrating injuries of the neck; and dental injuries.

Chapter 30, *Head and Spine Injuries*, discusses injuries specific to the head and to the spine and spinal cord, including traumatic brain injuries, skull fractures, and spine fractures. These injuries often occur in conjunction with facial trauma.

Anatomy and Physiology Review

Bones and Landmarks

The head is divided into two parts: the cranium and the face. The cranium, or skull, contains the brain. The face is composed of the eyes, ears, nose, mouth, and cheeks. The facial skeleton is composed of six major bones: the nasal bone, the two maxillae (upper jaw bones), the two zygomas (cheek bones), and the mandible (jaw bone) (**FIGURE 29-1**).

The mandible forms the jaw and chin (**FIGURE 29-2**). Motion of the mandible occurs at the **temporomandibular joint**, which lies just in front of the ear on either side of the face. The

semicircular **hyoid bone** “floats” in the superior aspect of the neck just below the mandible. Although not actually part of the face or skull, it supports and stabilizes the larynx and serves as a point of attachment for many important neck and tongue muscles.

The principal structures of the anterior region of the neck include the thyroid and cricoid cartilage, trachea, and numerous muscles and nerves (**FIGURE 29-3**). The firm prominence in the center of the anterior surface, commonly known as the Adam’s apple, is the upper part of the larynx, formed by the thyroid cartilage (**FIGURE 29-4**). The cricoid cartilage is a firm ridge of cartilage (the only complete circular cartilage structure of the trachea) found below the thyroid cartilage. Between the thyroid

FIGURE 29-1 The face is composed of six bones: the nasal bone, two maxillae, two zygomas, and the mandible.

YOU are the Provider

Part 1

While you and your partner are at the station, your partner remarks that he is surprised the ambulance has not been dispatched to a farming incident in the area because sugar beet harvest is in full swing. Just then, dispatch alerts you to a “machinery accident” at a beet field about 5 miles (8 km) west of town. You look at your partner with a knowing look on your face, then you begin your response. As you are responding, dispatch informs you that the fire department is also responding and that the patient is alert and oriented, with an unknown object stuck in his neck.

When you arrive on scene, you find the patient practically giving a hug to some type of farm implement. You can see a 3-foot (0.9-m) piece of round metal, approximately 0.5 inch (1 cm) in diameter, sticking out of the left side of his neck. It appears that the other end is still connected to the farm implement.

1. On the basis of the information provided to you, what are some possible injuries you may encounter?
2. What is the best way to remove the piece of metal from the machinery?

FIGURE 29-3 Important landmarks in the anterior region of the neck include the cricoid cartilage, the thyroid cartilage, the carotid arteries, the cricothyroid membrane, and the sternocleidomastoid muscles.

cartilage and the cricoid cartilage is a thin sheet of connective tissue (fascia)—the cricothyroid membrane—that joins the two cartilages.

The trachea connects the oropharynx and the larynx with the main air passages of the lungs

(the bronchi). Pulsations of the carotid arteries are easily palpable in a groove approximately 0.5 inch (1 cm) lateral to the larynx. Lying immediately adjacent to these arteries, but not palpable, are the internal jugular veins and several important nerves. Lateral to these vessels and nerves lie the **sternocleidomastoid muscles**, which allow movement of the head.

A series of bony prominences, known as the spines of the cervical vertebrae, lie posteriorly, in the midline of the neck. The lower cervical spines are more prominent than the upper ones. They are more easily palpable when the neck is in flexion.

The Eye

The eye is globe shaped, approximately 1 inch (2 cm) in diameter, and located within a bony socket in the skull called the orbit (**FIGURE 29-5**). The eyes are held in place by loose connective tissue and several muscles; these muscles control the movement of the eyes and are innervated by lower motor neurons that form three cranial nerves: the abducens, the trochlear, and the oculomotor.

FIGURE 29-5 The major components of the eye.

© Jones & Bartlett Learning.

The **oculomotor nerve** innervates most of these muscles and carries parasympathetic nerve fibers that cause constriction of the pupil and accommodation of the lens. The **optic nerve** provides the sense of vision.

The orbit forms the base of the floor of the cranial cavity, and directly above it are the frontal lobes of the brain. Between and below the orbits are the nasal bone and the sinuses, respectively. Therefore, any severe injury to the face or head can potentially damage the eyeball or the muscles attached to the eyeball that cause the eye to move.

The eyeball, or **globe**, keeps its global shape as a result of the pressure of the fluid contained within its two chambers. The anterior chamber is filled with **aqueous humor**, a clear watery fluid. If there is a loss of aqueous humor through a penetrating injury to the eye, then it will gradually be replenished. The posterior chamber is filled with **vitreous humor**, a jellylike substance that maintains the shape of the globe. If there is a loss of vitreous humor, then it cannot be replenished, and blindness may result. The white of the eye, called the **sclera**, extends over the surface of the globe.

The inner surface of the eyelids and the exposed surface of the eye itself, which are covered by a delicate membrane, the **conjunctiva**, are kept moist by fluid produced by the **lacrimal glands**, often called tear glands (**FIGURE 29-6**).

The opening in the center of the iris, which allows light to move to the back of the eye, is called the **pupil**. Like the opening in a camera, the pupil becomes smaller in bright light and larger in dim light. Normally, the pupils in both eyes are equal in size. Some people are born with pupils that are not equal (**anisocoria**); however, particularly in unresponsive

FIGURE 29-6 The lacrimal system consists of tear glands and ducts. Tears act as lubricant and keep the front of the eye from drying out.

© Jones & Bartlett Learning.

patients, unequal pupil size may indicate serious injury or illness of the brain or eye.

The Ear

The ear is a complex organ that is associated with hearing and balance. The ear is divided into three parts (**FIGURE 29-7**). The external ear is composed of the **pinna**, or auricle, which is the part lying outside of the head, and the external auditory canal, which leads in toward the tympanic membrane, or eardrum. The middle ear contains three small bones (the malleus, incus, and stapes) that move in response to sound waves hitting the tympanic membrane. It is connected to the nasal cavity by the eustachian tube, which permits equalization of pressure in the middle ear when external atmospheric pressure changes. The inner ear is composed of bony chambers filled with fluid. As the head moves, so does the fluid. In response, fine nerve endings within the fluid send impulses to the brain indicating the position of the head and the rate of change of position.

Pathophysiology

Injuries of the face and neck can often lead to partial or complete obstruction of the upper airway. Several factors may contribute to the obstruction. Because the face is highly vascular, bleeding from facial injuries can be very heavy, producing large

FIGURE 29-7 The ear has three principal parts: the external ear, composed of the pinna, external auditory canal, and tympanic membrane; the middle ear; and the inner ear, composed of bony chambers filled with fluid.

© Jones & Bartlett Learning.

blood clots in the upper airway that can lead to complete obstruction, particularly in a patient who is not fully alert. In particular, direct injuries to the nose and mouth, the larynx, or the trachea are often the source of significant bleeding or respiratory compromise. You may need to suction the airway if you are unable to control the bleeding. In addition, the injuries may cause loosened teeth or dentures to become dislodged into the throat, where they may be swallowed or aspirated. The swelling that often accompanies direct and indirect injury to the soft tissues in these areas can also contribute to airway obstruction.

The airway may also be affected when the patient's head is turned to the side, as often is done when the patient has an altered level of consciousness or is unresponsive. Other factors that interfere with normal respirations include possible injuries to the brain and/or cervical spine that may be associated with facial injuries. If the great vessels in the neck are injured, then significant bleeding and pressure on the upper airway are common; these can result in airway obstruction as well. In addition to causing massive bleeding and hemorrhagic shock, injury to any of these major vessels can produce cerebral hypoxia, infarct, air embolism, and permanent neurologic impairment.

Depending on the mechanism of injury (MOI), there may be a cervical spine injury. If there is significant impact to the face, suspect accompanying cervical spine injury and follow your agency's protocol for cervical injuries.

Special Populations

The proportionately larger amount of body surface area in the head and scalp of infants and toddlers increases the chances of injuries to the face and scalp, and a blood loss that results in this age group can quickly become significant. Consider the potential for shock and treat promptly and aggressively.

Soft-Tissue Injuries

Soft-tissue injuries of the face and neck are very common. Because the face and neck are extremely vascular, swelling in this area from soft-tissue injuries may be more severe than in other injured parts of the body and may cause airway compromise and ventilatory insufficiency. The skin and underlying tissues in these areas have a rich blood supply, so bleeding from penetrating injuries may be heavy.

FIGURE 29-8 Facial hematoma.

Courtesy of Rhonda Hunt.

FIGURE 29-9 A major avulsion injury is characterized by a large flap of skin that is peeled back from the underlying muscle and tissue.

© American Academy of Orthopaedic Surgeons.

Even minor soft-tissue wounds of the face and neck may bleed profusely. A blunt injury that does not break the skin may cause a break in a blood vessel wall, leading blood to collect under the skin; this is called a hematoma (**FIGURE 29-8**). In some situations, a flap of skin is peeled back, or avulsed, from the underlying muscle and fascia (**FIGURE 29-9**). Although open soft-tissue injuries to the face—lacerations, abrasions, and avulsions—by themselves are rarely life threatening, their presence, especially following a significant MOI, suggests the

potential for more severe injuries (eg, closed head and cervical spine injuries).

Maintain a high index of suspicion when a patient presents with closed soft-tissue injuries to the face, such as contusions and hematomas. These indicators of blunt-force trauma suggest the potential for more severe underlying injuries.

Impaled objects in the soft tissues or bones of the face may occur in association with facial trauma. Although these objects can damage facial nerves, the risk of airway compromise is of far greater consequence. This is especially true when an impaled object penetrates the cheek, because massive oropharyngeal bleeding can result in airway obstruction, aspiration, and ventilatory inadequacy. In addition, blood is a gastric irritant. Swallowing even a few tablespoons of blood can make a patient vomit, further increasing the likelihood of aspiration.

Words of Wisdom

Carefully assess a patient with soft-tissue injuries to the face, especially if the person has experienced a significant MOI. Although facial lacerations and avulsions are often the most obvious and dramatic injuries, they are usually not life threatening. Do not get tunnel vision or be fooled into thinking this is the patient's only injury.

Facial Fractures

Facial fractures commonly occur when the facial bones absorb the energy of a strong impact. The forces involved in some incidents may be massive; the magnitude of force required to fracture the maxilla (the upper jaw bone) will likely produce closed head injuries and cervical spine injuries as well. Therefore, when you assess a patient with a suspected facial fracture, protect the patient's cervical spine and monitor the patient's neurologic signs, specifically the level of consciousness.

A deep facial laceration should increase your index of suspicion that the underlying bone may have been fractured, and pain over a bone tends to support the suspicion of fracture. Other general signs and symptoms of facial fractures include ecchymosis, swelling, pain on palpation, crepitus, misalignment of the teeth, facial deformities or

Words of Wisdom

The magnitude of force required to fracture the maxilla can easily produce closed head injuries and cervical spine injuries as well!

asymmetry, instability of the facial bones, impaired ocular movement, and visual disturbances.

Nasal Fractures

Because the nasal bones are not as structurally sound as the other bones of the face, nasal fractures are the most common facial fracture. These fractures are characterized by swelling, tenderness, and crepitus when the nasal bone is palpated. Deformity of the nose, if present, usually appears as lateral displacement of the nasal bone from its normal midline position.

Nasal fractures, as with any facial fracture, are often complicated by the presence of an anterior or a posterior nosebleed (**epistaxis**), which can compromise the patient's airway.

Mandibular Fractures

Second only to nasal fractures in frequency, fractures of the mandible typically result from massive blunt-force trauma to the lower third of the face; they are particularly common following an assault injury. Because significant force is required to fracture the mandible, this structure may be fractured in more than one place and, therefore, unstable to palpation. In the case of a single fracture, the fracture site is most commonly located at the angle of the jaw. The site of multiple mandible fractures is usually the chin.

Mandibular fractures should be suspected in patients with a history of blunt force trauma to the lower third of the face who present with dental **malocclusion** (misalignment of the teeth), numbness of the chin, and inability to open the mouth. There will likely be swelling and ecchymosis over the fracture site, and teeth may be partially or completely avulsed. As the patient moves the jaw to speak and answer your questions, take note of the patient's symptoms of pain, such as decreased normal range of motion. In some patients, you might elicit tenderness, for example, by palpating specific locations on the mandible such as near the joints or specific impact points. This point tenderness and pain on motion can identify injuries that patients

might not have otherwise reported because they may be distracted by other wounds.

Temporomandibular joint dislocations may occur as a result of blunt force trauma to the lower third of the face, but this outcome is rare. Such dislocations are most often the result of exaggerated yawning or otherwise widely opening the mouth. Patients commonly feel a "pop" and then they cannot close their mouths; the mouth becomes locked in a wide-open position. The jaw muscles eventually go into spasm, causing severe pain.

Maxillary Fractures

Midfacial structures include the maxilla, zygoma, orbital floor, and nose. Maxillary fractures are most commonly associated with mechanisms that produce massive blunt facial trauma, such as MVCs, falls, and assaults. The signs include massive facial swelling, instability of the midfacial bones, malocclusion, and an elongated appearance of the patient's face.

Le Fort fractures are classified into three categories (**FIGURE 29-10**):

- **Le Fort I fracture.** A horizontal fracture of the maxilla that separates the hard palate and lower maxilla from the remainder of the skull.
- **Le Fort II fracture.** A fracture involving the nasal bone and inferior maxilla. A Le Fort II fracture separates the nasal bone and lower maxilla from the facial skull and remainder of the cranial bones.
- **Le Fort III fracture (**craniofacial disjunction**).** A fracture of all midfacial bones, separating the entire midface from the cranium.

Le Fort fractures can occur as isolated fractures or in combination, depending on the location of impact and the amount of trauma.

Orbital Fractures

The patient with an orbital fracture, such as a **blowout fracture** (**FIGURE 29-11**), may complain of double vision (**diplopia**) and lose sensation above the eyebrow or over the cheek because of associated nerve damage. This injury occurs when there is a fracture of one of the walls of orbit but the orbital rim remains intact, such as when a baseball or hockey puck strikes this region of the face during a sporting event.

The injury may cause the patient to have reduced sensation to areas that are innervated by the

FIGURE 29-10 Le Fort fractures. **A.** Le Fort I. **B.** Le Fort II. **C.** Le Fort III.

© Jones & Bartlett Learning.

FIGURE 29-11 A blowout fracture of the left orbit.

© Jones & Bartlett Learning.

infraorbital nerve. The affected area extends from the tip of the nose, including the nares, and follows the margin of the maxilla, curving up to meet the temple. Also, the eyeball may retract posteriorly into the space created when the cavity is enlarged. Massive nasal discharge may occur, and vision is often impaired. Fractures of the inferior orbit are the most common type and can cause paralysis of upward gaze (the patient's injured eye will not be able to follow your finger above the midline).

Zygomatic Fractures

Fractures of the zygomatic bone (cheekbone) commonly result from blunt trauma in MVCs and assaults. When the zygomatic bone is fractured, that side of the patient's face appears flattened, and there is loss of sensation over the cheek, nose, and upper lip; paralysis of upward gaze may also be

TABLE 29-1 Summary of Facial Fractures	
Injury	Signs and Symptoms
Multiple facial bone fractures	• Massive facial swelling/ecchymosis • Dental malocclusion (misalignment of teeth) • Palpable deformities and/or asymmetry • Anterior or posterior epistaxis
Zygomatic and orbital fractures	• Loss of sensation below the orbit • Flattening of the patient's cheek • Paralysis of upward gaze • Visual disturbances
Nasal fractures	• Crepitus and instability • Swelling, tenderness, lateral displacement • Anterior or posterior epistaxis
Maxillary (Le Fort) fractures	• Mobility of the facial skeleton • Dental malocclusion • Facial swelling
Mandibular fractures	• Dental malocclusion • Mandibular instability

© Jones & Bartlett Learning.

present. Other injuries and conditions commonly associated with zygomatic fractures include orbital fractures, ocular injury, and epistaxis.

TABLE 29-1 summarizes the characteristics of various facial fractures.

Dental Injuries

Fractured and avulsed teeth are common following facial trauma. Dental injuries may be associated with mechanisms that cause severe maxillofacial trauma (eg, MVC), or they may occur in isolation (eg, a direct blow to the mouth from an assault). Always assess the patient's mouth following a facial injury, especially if your examination reveals fractured or avulsed teeth. Teeth fragments (or even whole teeth) can become an airway obstruction and should be removed immediately from the patient's mouth. In contrast, you should leave well-fitting dentures in place.

Patient Assessment

Scene Size-up

As you arrive on the scene, observe for hazards and threats to the safety of the crew, bystanders, and the patient. Assess the impact of hazards on patient care, and address those hazards. Assess for the potential for violence and assess for environmental hazards.

Patients who are alert and supine and have oral or facial bleeding may protect their airways by coughing, projecting the blood at you. Therefore, take standard precautions that require eye protection and a face mask. Also, put several pairs of gloves in your pocket for easy access in the event your gloves tear or you must treat multiple patients with bleeding.

If the incident involves an MVC, then you may be confronted with more than one patient in a vehicle. Determine the number of patients and consider if you need additional or specialized resources on the scene.

Safety

Even minor facial injuries may result in copious bleeding. Always wear proper protective equipment.

As you observe the scene, look for indicators of the MOI. This assessment helps you develop an early index of suspicion for underlying injuries in a patient who has sustained a significant MOI. As you put together information from dispatch and your

observations of the scene, consider how the MOI produced the injuries expected. Common MOIs for face and neck injuries include MVCs, sports, falls, penetrating trauma, and blunt trauma. In MVCs, the probability of injury increases if the vehicle rolled over or came to an abrupt stop when striking an immovable object, such as a tree.

Primary Survey

The primary survey focuses on identifying and managing life-threatening concerns. *Do not let soft-tissue injuries distract you from life threats that may not be readily apparent.* Scene safety must always be first. After establishing scene safety, address any immediately obvious exsanguinating hemorrhage. Then begin the standard progression through the primary survey to include assessment and treatment of airway, breathing, and circulation.

As you approach the patient, look for important indicators to alert you to the seriousness of the patient's condition. For example, is the patient interacting with the environment or lying still, making no sounds? Assess for readily apparent life threats such as significant bleeding and signs such as changes in skin color. Combative or aggressive behavior can be a sign of a closed head injury. The general impression will help you develop an index of suspicion for serious injuries and determine your sense of urgency for medical intervention. If the patient has a potential neck or spine injury, then assign a crew member to achieve and maintain manual stabilization. Always check for responsiveness using the AVPU (Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive) scale.

Ensure the patient has a clear and patent airway as soon as you arrive at the patient's side. Suction any blood, fluid, or vomit until the airway is clear. Teeth fragments (or even whole teeth) can become an airway obstruction and must be removed from the patient's mouth without delay. If the patient is unresponsive or has a significantly altered level of consciousness, then consider inserting a properly sized airway adjunct, such as an oropharyngeal airway. The use of a nasopharyngeal airway is controversial and is relatively contraindicated in the presence of midface trauma, as it is possible for it to penetrate the brain through a fracture. A nasopharyngeal airway should not be used in any patient

with suspected nasal fractures or in patients with cerebrospinal fluid (CSF) or blood leakage from the nose or with any evidence of midface trauma, unless absolutely necessary. As always, be aware of and follow your local protocols.

Quickly assess for adequacy of breathing. Determine whether the patient's breathing is abnormally slow or rapid, or excessively deep or shallow. An inadequate depth or rate that results in compromised breathing should prompt you to take immediate action. Advanced airway management may be needed. Assess for any injuries of the chest that may impede breathing, such as a flail segment or an open wound.

Words of Wisdom

Any patient who is having difficulty breathing should receive oxygen. If respirations are adequate, then administer oxygen as needed to maintain an oxygen saturation level of 94% or greater. However, *always treat the patient* and not a diagnostic tool. Pulse oximeters may show false readings in the presence of poor perfusion, carbon monoxide, and other circumstances.

Face and throat injuries increase the need for aggressive airway maintenance. Airway management can be especially challenging in patients with massive facial injuries. Oropharyngeal bleeding poses an immediate threat to the airway, and unstable facial bones can hinder your ability to maintain an effective mask-to-face seal for bag-mask ventilation. Still, airway and breathing take priority over soft-tissue injuries. Note the importance of suctioning, and remember to reassess airway patency frequently. Call early for paramedic backup because endotracheal intubation (a paramedic skill) may be the method of choice for airway protection. If an airway cannot be established, paramedics may need to perform a surgical airway (ie, cricothyrotomy) to ventilate the patient.

Quickly palpate the pulse for rate and quality; determine the skin condition, color, and temperature; and check the capillary refill time. Significant bleeding is an immediate life threat and must be controlled quickly using the appropriate methods. Expose the patient and perform a rapid full-body scan prior to packaging the patient for transport.

If the patient you are treating has an airway or a breathing problem or significant bleeding, then you must consider rapid transport to the closest, most

YOU are the Provider

Part 2

You begin your assessment of the patient and find that he is alert and oriented, and surprisingly calm, given the circumstances. He states he was attempting to free an obstruction in the piece of equipment when a tension rod broke free and impaled him in the neck. He states "it's getting hard to breathe" and that he has to "hug" the machine to keep from falling over. You instruct your partner to place the patient on a nonrebreathing mask with oxygen at 15 L/min. Fire department personnel arrive on scene, and after a brief meeting with the incident commander, he agrees with your recommendation to remove the tension rod, very carefully, from the implement. Prior to the removal, you need to attempt to secure the object in the patient's neck. You ask one of the available firefighters to maintain manual stabilization of the head.

Recording Time: 1 Minute

Appearance	No apparent acute distress
Level of consciousness	Alert and oriented
Airway	Patent, with possible obstruction
Breathing	Difficult to assess; appears equal on both sides and adequate
Circulation	Warm and dry

- How would you secure the tension rod to the patient?
- Why should you be concerned about air entering the wound?

Words of Wisdom

If significant trauma has likely affected multiple body systems, then expose the patient and perform a rapid exam to ensure you have found all significant injuries. A 60- to 90-second rapid full-body scan may identify factors that help you determine whether the patient requires prompt transport. Begin with the head and neck, while a partner is manually holding the head in place. When you are done, apply a cervical collar if you have not done so already and it is indicated by the patient presentation. If you identify life-threatening conditions or those that have the potential to become unstable, such as a distended abdomen or femur fracture, then the patient requires rapid and immediate transport to the closest, most appropriate facility.

appropriate facility. Stabilizing and maintaining the airway and breathing and controlling bleeding can be very difficult in patients with facial or neck injuries. Avoid delays in transport, and consider paramedic backup or air transport if the transport time is long.

A patient with signs and symptoms of internal bleeding must be transported quickly to the appropriate hospital for surgical evaluation. Internal bleeding in face and throat injuries may compromise blood flow to the brain. Bleeding from the brain or major vessels of the throat can have a serious impact on the patient's airway. The condition of a patient with significant external bleeding or signs of significant internal bleeding may quickly become unstable. Treatment is directed at addressing immediate life threats and providing rapid transport to the closest appropriate hospital. If the patient is initially considered to be stable, then frequently reassess the patient and upgrade to rapid transport if the patient's condition worsens. Remember, any significant blow to the face or throat should increase your index of suspicion for a spinal or brain injury.

Provide rapid transport for any patient who presents with the following:

- Signs of hypoperfusion (tachycardia, tachypnea, weak pulse, pale/cool/moist skin, and/or hypotension)
- A significant MOI but in stable condition
- A poor general impression

- Any alteration in level of consciousness
- Abnormal vital signs
- Dyspnea
- Severe pain
- Isolated injuries to the eye

In some situations, surgical intervention and/or restoration of circulation to the eye will be required within 30 minutes or permanent blindness may result. Consider transporting the patient with serious, isolated eye injuries to an eye care specialty center depending on your local protocol.

In any patient with a significant MOI, maintain a high index of suspicion for internal injuries and shock, and transport the patient early. Do not wait for signs of shock to develop. Continue to maintain a high index of suspicion, and reassess your priority and transport decision as needed. Do not delay transport of a seriously injured patient, particularly one with significant bleeding even if controlled, to take the patient's history or perform a secondary assessment. Further assessment can continue during transport.

Words of Wisdom

Always consider the possibility of spinal injuries in patients with face and neck injuries.

History Taking

After the life threats have been managed during the primary survey, investigate the chief complaint or history of present illness. Obtain a medical history and be alert for injury-specific signs and symptoms, as well as any pertinent negatives such as no pain or no loss of sensation.

Next, obtain a SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history from the patient. Any information you obtain at this point will be valuable if the patient becomes unresponsive. If the patient is not responsive, then attempt to obtain the SAMPLE history from friends or family members who may be present. Otherwise, you may have to rely on your assessment and any medical alert jewelry or identification you find.

In an unresponsive patient, you will only be able to observe the signs of the patient's injuries. Any other information will need to be obtained from someone who is knowledgeable about the patient. Keep in mind the information you obtain may or may not be accurate and may be incomplete. The person providing the information may not be able to give you the actual names of the patient's medications but might be able to provide some pertinent medical history and possibly, known allergies. Always document who gave you the information, and use quotation marks to indicate direct quotes.

Secondary Assessment

If significant trauma has likely affected multiple systems in the patient, then start with a rapid full-body scan looking for DCAP-BTLS (Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, Swelling) to confirm that you have found all life threats and injuries. When this step is completed, perform a detailed full-body exam. However, do not delay transport to complete a thorough physical examination.

Special Populations

In the geriatric population, poor skin tone and loss of body fat can produce significant soft-tissue injury in the presence of even a simple MOI. Anticoagulation therapy in older adult patients can lead to significant blood loss from minor insults. Additionally, normally trivial physical findings, such as bruises and minor lacerations, can be signs of severe underlying trauma such as traumatic brain injury.

In a responsive patient who has an isolated injury with a limited MOI, a head-to-toe exam is still necessary, but consider giving extra attention to the isolated injury, the patient's chief complaint, and the body region affected—in this case, the face and throat. Ensure your control of bleeding is maintained and note the location of the injury. Inspect open wounds for any foreign matter and stabilize impaled objects.

During the physical examination, look for swelling, deformities of the bones, contusions, and

Special Populations

Relative to younger, healthy adults, older adult patients are at high risk for severe epistaxis following even minor facial injuries, especially patients with a history of hypertension or anticoagulant medication use (such as aspirin). This bleeding often originates in the posterior nasopharynx and may not be grossly evident during your assessment.

discoloration. Also gently palpate the face, looking and feeling for any abnormalities such as deformity or tenderness. Ask yourself the following questions:

1. Do the facial bones seem to be in alignment?
2. Does the nasal bone seem to deviate from the midline?
3. Note any variations from the normal facial examination; is there any facial drooping?
4. Does one eye appear to be lower than the other? If so, this is an indication of an orbital fracture.
5. Does the mandible appear to deviate toward one side or the other?

If the patient is responsive, then explain exactly what you are doing and what you are looking for. Your discovery of an abnormality may actually be an old injury that the patient can describe to you in more detail.

Assess all underlying systems. This assessment should include the neurologic system, including brain and major nerves; sensory organs, including the eyes and nose; the respiratory system, including mouth, nose, sinuses, and airway; and the circulatory system, particularly focusing on the carotid arteries and jugular veins.

When you evaluate the eyes, start on the outer aspect of the eye and work your way in toward the pupils. Examine the eye for any obvious foreign matter. The patient may relay pertinent information about this possibility to you ("I have something in my eye."). Quickly assess the patient's visual acuity—that is, the clarity of the patient's vision in each eye. Note any discoloration of the eye, bleeding in the iris area, or redness. Look for eye symmetry; asymmetry is a possible indication of a brain injury.

Look at each pupil for equal size and reaction to light. If the pupils are not symmetric, then ask the

patient whether there is any history of eye surgeries or injuries. Previous surgery or injury, rather than brain injury, may be the root cause of the pupils not appearing the same. Cataract surgery can cause unequal pupils, but in a patient with a suspected head injury or ocular injury, anisocoria (unequal pupils in dim light) may be present. Determine whether the unequal pupils are caused by physiologic or pathologic issues. Using over-the-counter eye drops can change pupil size, and certain asthma inhalers can have the same effect if inadvertently sprayed into the eye. Brain injury, nerve disease, glaucoma, and meningitis are all possible causes of unequal pupils.

Assessment Pearls

- Airway! Airway! Airway! Pay close attention to the airway of any patient with facial trauma and bleeding. You may spend most of the transport time suctioning to keep the airway patent.
- Be prepared for the patient to vomit. Swallowing blood often causes emesis, so have suction readily available and be prepared to tilt the backboard to the side if the patient is immobilized.
- When you treat an eye injury, remember to cover both eyes because they move consensually.
- Follow local protocols for spinal motion restriction. Not all patients need full immobilization.
- Examine the area to be covered prior to applying a cervical collar so as not to hide any injuries.
- Evaluate the pupils, but if pupils are unequal and the patient is alert and oriented, question the patient about a history of anisocoria.
- Always use an occlusive dressing on penetrating neck injuries and evaluate thoroughly for signs of swelling or subcutaneous emphysema.

Check whether the patient can follow your finger from side to side as well as up and down, and whether the patient can read normal print. Note whether the patient reports blurry vision in either eye or a new sensitivity to light.

Assess vital signs to obtain a baseline so you can observe any changes the patient may display during treatment. A systolic blood pressure reading of less than 90 mm Hg with a weak, rapid pulse and cool, moist skin that is pale or gray should alert you to the presence of hypoperfusion in a patient who may

have significant bleeding. Remember, you must be concerned with both visible bleeding and unseen bleeding inside a body cavity. With facial and throat injuries, baseline information about the rate and quality of respirations and pulse is very important, as is monitoring throughout patient care.

In addition to conducting a hands-on assessment, use monitoring devices to quantify the patient's oxygenation and circulatory status. You may also use noninvasive methods to monitor blood pressure. It is recommended that you always assess the patient's first blood pressure manually—that is, using a sphygmomanometer (blood pressure cuff) and stethoscope. Use a glucometer to assess blood glucose levels. An altered mental status in a trauma patient could be the result of hypoglycemia.

Words of Wisdom

Do not rely on diagnostic tools and forget to consider the condition of the patient. Pulse oximeters are not accurate if the patient has decreased perfusion. Treat the patient and not the device.

Reassessment

Repeat the primary survey. Reassess the patient's vital signs and chief complaint. In addition, continually reassess the adequacy of the patient's airway, breathing, and circulation. Recheck patient interventions. Are the treatments you provided for problems with the ABCs still effective? This consideration is particularly important in patients with facial or neck injuries because such injuries often affect associated systems, such as the respiratory (airway and breathing), circulatory, and nervous systems. Reassess the patient's condition at least every 5 minutes.

In your documentation, describe the MOI and the position in which you found the patient when you arrived at the scene. Document the method used to remove the patient from the vehicle, for example, "prolonged extrication." In patients with severe external bleeding, it is important to recognize, estimate, and report the amount of blood loss that has occurred and to indicate how rapidly or how much time has passed since the bleeding started. This task can be challenging, especially if the patient

is lying on a wet surface or one that absorbs fluids, or if the environment is dark.

Call early to inform the hospital personnel about the various injuries involving the patient's head and neck. Specialists may need to be called to manage injuries involving the eyes, ears, teeth, mouth, sinuses, larynx, esophagus, or large vessels. These specialists are not always in the hospital, especially during the evening or night, or in smaller hospitals, so informing emergency department (ED) personnel of all injuries involving the face and throat can save valuable time.

Emergency Medical Care

Provide complete spinal immobilization to any patient with suspected spinal injuries. Spinal injuries should be suspected whenever a patient experiences significant trauma to the face or neck. Maintain an open airway, be prepared to suction the patient, and consider placement of an oropharyngeal airway. Whenever you suspect significant bleeding, administer high-flow oxygen. Oxygen and airway maintenance are important for all patients

with face and neck injuries. If needed, provide assisted ventilation using a bag-mask device with high-flow oxygen. The criteria for spinal immobilization are discussed in Chapter 30, *Head and Spine Injuries*.

Control any significant visible bleeding. If the patient has signs of hypoperfusion, then aggressively treat the patient for shock and provide prompt transport to the closest, most appropriate facility. Do not delay transport of a seriously injured trauma patient to complete non-life-saving treatments in the field, such as splinting extremity fractures. Instead, complete these treatments en route to the hospital. If a spinal column injury is not suspected, the patient may be more comfortable and the airway may be easier to maintain in the sitting position during transport.

Gain intravenous access with one or two large-bore catheters, and give a 20-mL/kg bolus of an isotonic crystalloid solution to maintain radial pulses if signs of hypoperfusion are apparent. Ensure you follow local protocols, and do not delay transport in an effort to gain intravenous access on scene. Obtain vascular access en route if the patient is in

YOU are the Provider

Part 3

You place an occlusive dressing around the rod to reduce the chances of an air embolism, should an artery or vein be severed. After securing the dressing in place, you apply copious amounts of bulky dressings over the top of the occlusive dressing in an attempt to secure the rod as best as you can while fire department personnel begin to cut the distal end. Fire department personnel have chosen to use a hacksaw in an attempt to minimize movement to the rod and to minimize the transfer of heat. When they are approximately 80% through the rod, you note an increased amount of blood coming from the wound. You fear this may be arterial blood, so you ask fire department staff to immediately cease operations so you can assess the bleeding.

Recording Time: 8 Minutes

unstable condition. As discussed in Chapter 14, *Shock*, management of shock can be controversial in trauma patients.

Assessment and Management of Specific Injuries

Soft-Tissue Injuries

All face and neck injuries are potentially serious. The emergency care of soft-tissue injuries to the face and neck must focus on protecting the airway. You should assess the ABCDEs and care for any life threats first. Remember to take standard precautions in all cases.

In the absence of life-threatening bleeding, your first step is to open and clear the airway. Securing and maintaining a patent airway is paramount. Because blood draining into the throat can produce vomiting and airway obstruction, the patient may need frequent suctioning. Take appropriate precautions if you suspect the patient has sustained a cervical spine injury; ensure you avoid moving the neck. Use the jaw-thrust maneuver to open the patient's airway, and then suction the mouth. Once you immobilize the patient in a cervical collar and on a backboard, you can turn the backboard to one side to allow any blood or vomitus to drain out of the mouth rather than allowing it to pool in the pharynx and obstruct the airway.

Although most open soft-tissue injuries are not serious, if not appropriately treated, they can lead to substantial blood loss and even shock. However, if you effectively treat open soft-tissue injuries, then you can minimize common complications such as bleeding, shock, pain, and infection. Expose all wounds, control bleeding, and be prepared to treat the patient for shock.

Control external bleeding by applying direct manual pressure with a dry, sterile dressing. Use roller gauze, wrapped around the circumference of the head, to hold a pressure dressing in place (**FIGURE 29-12**). Do not apply excessive pressure if an underlying skull fracture might potentially be present. When an injury exposes the brain, eye, or other structures, cover the exposed parts with a moist, sterile dressing to protect them from further damage. When treating eye injuries, always cover both eyes. For injuries in which the skin is not

FIGURE 29-12 Use roller gauze, wrapped around the circumference of the head, to hold a pressure dressing in place.

© Nancy G Fire Photography, Nancy Greifenhagen/Alamy Stock Photo.

broken, apply ice packs locally to help control the swelling of bruised tissues.

Treat facial lacerations and avulsions as you would any other soft-tissue injury. Control all bleeding with direct pressure and apply sterile dressings. If you suspect the patient has an underlying facial fracture, then apply just enough pressure to control the bleeding.

If the patient has soft-tissue injuries around the mouth, then check for bleeding inside the mouth. Broken teeth and lacerations to the tongue may cause profuse bleeding and obstruction of the upper airway (**FIGURE 29-13**). Often, the patient will swallow the blood from lacerations inside the mouth, so the hemorrhage may not be apparent. You should also inspect the inside of the mouth for bleeding and hidden injuries in patients who have sustained facial trauma. Remember, patients who swallow blood are prone to vomiting.

Often, physicians will be able to graft a piece of avulsed skin back into the appropriate position. For this reason, if you find portions of avulsed skin that have become separated, if possible wrap them in a sterile dressing moistened with saline to prevent drying, place them in a plastic bag, and keep them cool. Never place tissue directly on ice; freezing will

FIGURE 29-13 Soft-tissue injuries around the mouth can be associated with profuse bleeding inside the mouth and obstruction of the airway.

destroy the tissue and make it unusable. Deliver the bag labeled with the patient's name to the ED along with the patient. In many avulsion injuries, the skin will still be attached in a loose flap (**FIGURE 29-14**). Place the flap in a position that is as close to normal as possible, and hold it in place with a dry,

FIGURE 29-15 Normally, the pupils are round, equal in size, and equally reactive when exposed to light. The pupils shown here appear unequal.

sterile dressing. These steps will help to increase the patient's chances of having normal appearance restored.

Injuries of the Eyes

Eye injuries are common, particularly in sports. An eye injury can produce severe, lifelong complications, including blindness. Proper emergency medical treatment will minimize pain and may very well help to prevent permanent vision loss.

In a normal, uninjured eye, the entire circle of the iris is visible. The pupils are round, usually equal in size, and react equally when exposed to light (**FIGURE 29-15**). Both eyes move together in the same direction when following your moving finger. After an injury, however, pupil reaction or shape and eye movement are often disturbed. Any of these conditions should cause you to suspect an injury of the globe or its associated tissues. However, remember that abnormal pupil reactions sometimes are a sign of brain injury rather than eye injury.

Treatment starts with a thorough examination to determine the extent and nature of any damage. Always perform your examination taking standard precautions to avoid aggravating any problems. Look for specific abnormalities or conditions that may suggest the nature of the injury (**FIGURE 29-16**). For example, blunt or penetrating injuries can produce swollen or lacerated eyelids. Bleeding soon after irritation or injury can result in a bright red conjunctiva. A damaged cornea quickly loses its smooth, wet appearance.

A

B

C

FIGURE 29-16 Injuries to the eyes are easily detected by swelling (A), bleeding (B), and the presence of foreign objects in the eye (C).

A & B: © Jones & Bartlett Learning; C: © American Academy of Orthopaedic Surgeons.

Foreign Objects

Large objects are prevented from penetrating the eye by the protective orbit that surrounds it. However, moderately sized and smaller foreign objects of many different types can enter the eye

and cause significant damage. Even a very small foreign object, such as a grain of sand lying on the surface of the conjunctiva, may produce severe irritation. The conjunctiva becomes inflamed and red—a condition known as **conjunctivitis**—almost immediately, and the eye begins to produce tears in an attempt to flush out the object. Irritation of the cornea or conjunctiva causes intense pain. Patients may have difficulty keeping their eyelids open because the irritation is further aggravated by bright light.

If a small foreign object is lying on the surface of the patient's eye, you should use a normal saline solution to gently irrigate the eye. Irrigation with a sterile saline solution will frequently flush away loose, small particles. If a small bulb syringe is available, you can use it, or a nasal airway or cannula, to direct the saline into the affected eye. Always flush from the nose side of the eye toward the outside to avoid flushing material into the other eye. After it has been flushed away, a foreign body will often leave a small abrasion on the surface of the conjunctiva. For this reason, the patient may report irritation even when the particle itself is gone. It is always a good idea to transport the patient to the hospital for further assessment to ensure appropriate medical care to the affected eye.

Words of Wisdom

Large and small foreign bodies, particularly small metal fragments, can become completely embedded in the globe. The patient may not even be aware of the cause of the problem. Suspect such an injury when the patient's history includes metal work (eg, hammering, exposure to splinters, grinding, or vigorous filing) and when you observe signs of ocular injury (eg, redness, irritation, inflammation).

Gentle irrigation usually will not wash out foreign bodies that are stuck to the cornea or lying under the upper eyelid. When you examine the undersurface of the upper eyelid, pull the lid upward and forward. If you spot a foreign object on the surface of the eyelid, then try to remove it with a moist, sterile, cotton-tipped applicator, as shown in **SKILL DRILL 29-1**. Never attempt to remove a foreign body that is stuck to the cornea.

Skill Drill 29-1 Removing a Foreign Object From Under the Upper Eyelid

Step 1

Have the patient look down, grasp the upper lashes, and gently pull the lid away from the eyeball.

Step 2

Place a cotton-tipped applicator horizontally on the outer surface of the upper eyelid.

Step 3

Pull the eyelid forward and up, fold it back over the applicator and expose the undersurface of the eyelid.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 4

Gently remove the foreign object from the eyelid with a moistened, sterile, cotton-tipped applicator.

Foreign bodies ranging in size from a pencil to a sliver of metal may be impaled in the eye. These objects must be removed by a physician. As an AEMT, your care involves stabilizing the object and preparing the patient for transport to definitive care. The greater the length of the foreign object you can see sticking out of the eye, the more important stabilization becomes in avoiding further damage. Bandage the object in place to support it. Cover the eye

with a moist, sterile dressing, and then surround the object with a doughnut-shaped collar made from roller gauze or a small gauze pack. Cover the noninjured eye to prevent consensual movement and further damage of the injured eye. Follow the steps in **SKILL DRILL 29-2**.

If you see or suspect an impaled object in the eye, bandage both eyes with soft bulky dressings to prevent further injury to the affected eye. Your

Skill Drill 29-2 Stabilizing a Foreign Object Impaled in the Eye

Step 1

To prepare a doughnut ring, wrap a 2-inch (5-cm) roll around your fingers and thumb seven or eight times. Adjust the diameter by spreading out your fingers or by squeezing them together.

Step 2

Remove the gauze from your hand and wrap the remainder of the gauze roll radially around the ring that you have created.

Step 3

Work around the entire ring to form a doughnut.

Step 4

Carefully place the ring over the eye and impaled object to stabilize the impaled object in place, and then secure it with a roller bandage.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

bandage should be loose enough to hold the eyelid closed but should not cause pressure on the eye itself. This bandaging technique prevents **sympathetic eye movement** (the movement of one eye causing both eyes to move), which may cause additional damage to the injured eye. An embedded object in the eye must be handled by an ophthalmologist on an urgent basis. Radiographs and

special equipment may be required to find the foreign body.

Burns of the Eye

Chemicals, heat, and light rays all can burn the delicate tissues of the eye, such as the cornea, often causing permanent damage. Your role is to stop the burn and prevent further damage.

A

B

FIGURE 29-17 **A.** Chemical burns typically occur when an acid or alkali is splashed into the eye. **B.** This figure shows a chemical burn from lye, an alkaline solution. Because lye can continue to damage the eye even when it is diluted, fast action is needed.

© Paul Whitten/Science Source.

Chemical Burns

Chemical burns, usually caused by acid or alkaline solutions, require immediate emergency medical care (**FIGURE 29-17**). Treatment consists of flushing the eye with water or a sterile saline irrigation solution. If sterile saline is not available, then you can use any clean water.

When treating a chemical burn, the idea is to direct the greatest amount of irrigating solution or water into the eye as gently as possible (**FIGURE 29-18**). Because opening the eye spontaneously may cause pain, you may have to force the patient's lids open to irrigate the eye adequately. Ideally, you will use a

bulb or irrigation syringe, a nasal cannula, or some other device that will allow you to control the flow; however, in some circumstances, you may have to resort to pouring water into the eye by holding the patient's head under a gently running faucet. You can even have patients immerse their face in a large pan or basin of water and rapidly blink the affected eyelid. If only one eye is affected, then take care to avoid getting contaminated water into the unaffected eye.

Irrigate the eye for at least 5 minutes. Flush from the inner corner of the affected eye toward the outside corner. Never flush from the outside corner, as this technique may cause the substance to contaminate the unaffected eye. If the burn was caused by an alkali or a strong acid, then irrigate the eye continuously for 20 minutes. Follow local protocols on whether to try to irrigate while transporting or to stay on scene until flushing is complete. Strong acids and all alkaline solutions can penetrate deeply, requiring a prolonged flush. Again, always take care to protect the uninjured eye during this process.

After you have completed the irrigation, apply a clean, dry dressing to cover the eye, and transport the patient promptly to the hospital for further care (**FIGURE 29-19**). If the irrigation can be carried out satisfactorily in the ambulance, it should be done during transport to save time.

Thermal Burns

When a patient is burned on the face during a fire, the eyes usually close rapidly because of the heat. This reaction is a natural reflex to protect the eye from further injury. However, the eyelids remain exposed and are frequently burned (**FIGURE 29-20**). Burns of the eyelids require very specialized care. It is best to provide prompt transport for these patients without further examination. First, however, you should cover both eyes with a sterile dressing moistened with sterile saline. You may apply eye shields over the dressing.

Light Burns

Infrared rays, eclipse light (if the patient has looked directly at the sun), and laser burns all can cause significant damage to the sensory cells of the eye when rays of light become focused on the retina. Retinal injuries that are caused by exposure to extremely bright light are generally not painful but may result in permanent damage to vision.

FIGURE 29-19 Apply a clean, dry dressing to cover the eye after you have finished irrigation.

© American Academy of Orthopaedic Surgeons.

Superficial burns of the eye can result from ultraviolet rays from an arc welding unit; light from prolonged exposure to a sunlamp; or reflected light

from a bright, snow-covered area (snow blindness). Initially, this kind of burn is not painful but may become so 3 to 5 hours later, when the damaged cornea responds to the injury. Severe conjunctivitis usually develops, with redness, swelling, and excessive tear production. You can ease the pain from these corneal burns by covering each eye with a sterile, moist pad and an eye shield. Have the patient lie down during transport to the hospital, and protect the patient from further exposure to bright light. The patient should be examined by a physician as soon as possible.

Lacerations

Lacerations of the eyelids require very careful repair to restore appearance and function. Bleeding may be heavy, but it usually can be controlled by gentle, manual pressure. If there is a laceration of the globe

A

B

FIGURE 29-20 Thermal burns occasionally cause significant damage to the eyelids. **A.** Arrows show some full-thickness burns. **B.** Burns of the eyelids require immediate hospital care.

A: © American Academy of Orthopaedic Surgeons; B: Reproduced from Sarabahi S, Kanchana K. Management of ocular and periocular burns. *Ind J Burns*. 2014;22(1):22.

A

B

FIGURE 29-21 Lacerations are serious injuries that require prompt transport. **A.** Although bleeding can be heavy, never exert pressure on the eye. **B.** Pressure may squeeze the vitreous humor, iris, lens, or even the retina out of the eye.

A: © Sergey Lykov/EyeEm/Getty Images; B: © Paul Whitten/Science Source.

itself, then apply no pressure to the eye; compression can interfere with the blood supply to the back of the eye and result in loss of vision from damage to the retina. Furthermore, pressure may squeeze the vitreous humor, iris, lens, or even the retina out of the eye and cause irreparable damage or blindness (**FIGURE 29-21**).

Follow these three important guidelines in treating penetrating injuries of the eye:

1. Never exert pressure on or manipulate the injured eye (globe) in any way.

2. If part of the eyeball is exposed, gently apply a moist, sterile dressing to prevent drying.
3. Cover the injured eye with a protective metal eye shield, cup, or sterile dressing. Apply soft dressings to both eyes, and provide prompt transport to the hospital.

On rare occasions following a serious injury, the globe may be displaced (avulsed) out of its socket. Do not attempt to manipulate or reposition it in any way! Simply cover the protruding eye and stabilize it with a moist, sterile dressing (**FIGURE 29-22**).

A

B

FIGURE 29-22 An injury that exposes the brain (A), eye (B), or other structures should be covered with a moist, sterile dressing to prevent further damage.

A: © E.M. Singletary, M.D. Used with permission; B: © American Academy of Orthopaedic Surgeons.

Remember to cover both eyes to prevent further injury because of sympathetic eye movement. Have the patient lie in a supine position en route to the hospital to prevent further loss of fluid from the eye.

Blunt Trauma

Blunt trauma can cause serious eye injuries. These range from the ordinary “black eye,” characterized by bleeding into the tissue around the orbit, to a severely damaged globe (**FIGURE 29-23**). You may see an injury called **hyphema**, or bleeding into the anterior chamber of the eye, that obscures part or all of the iris (**FIGURE 29-24**). This injury is common in blunt trauma and may seriously impair vision. Cover the eye to protect it from further injury and transport the patient to the hospital for further medical evaluation.

FIGURE 29-23 The typical “black eye” is caused by bleeding into the tissue around the orbit.

© Berit Skogmo/Stock/Thinkstock/Getty Images.

Hyphema or rupture of the globe indicates that a significant amount of force was applied to the face and, therefore, may signal the presence of a spinal injury. Elevate the head of the backboard to approximately a 40° angle to decrease intraocular pressure (IOP), and discourage the patient from performing activities that may increase IOP (eg, coughing).

Blunt trauma can also cause a fracture of the orbit, particularly of the bones that form its floor and support the globe. Such an injury is called a blowout fracture. The fragments of fractured bone can entrap some of the muscles that control eye movement, causing double vision (**FIGURE 29-25**). Any patient who reports pain, double vision, or decreased vision following a blunt injury about the eye should be placed on a stretcher and transported promptly to the ED. Protect the eye from further injury with a metal shield; cover the other eye to minimize movement on the injured side.

Another possible result of blunt eye injury is **retinal detachment**, or separation of the inner layers of the retina from the underlying choroid (the vascular membrane that nourishes the retina). This injury is often seen in sports, especially boxing. It is painless but produces flashing lights, specks, or

A

B

FIGURE 29-24 A. A hyphema, characterized by bleeding into the anterior chamber of the eye, is common following blunt trauma to the eye. This condition may seriously impair vision and should be considered a sight-threatening emergency. **B.** Illustration of hyphema.

FIGURE 29-25 A patient with a blowout fracture may not move the eyes together because of muscle entrapment. Therefore, the patient sees double images of any object.

© American Academy of Orthopaedic Surgeons.

“floaters” in the field of vision and a cloud or shade over the patient’s vision. Because it can cause devastating damage to vision, retinal detachment is an ocular emergency and requires urgent medical treatment to preserve vision in the eye.

Words of Wisdom

Anisocoria, a condition in which the pupils are not of equal size, is a significant finding in patients with ocular injuries or traumatic brain injury. However, simple or physiologic anisocoria occurs in approximately 20% of the population.¹ Usually, the patient’s pupils differ in size by less than 0.5 mm; however, some people have pupils that vary in size up to 1 mm.² This is not a clinically significant finding.

Unilateral cataract surgery may also cause unequal pupil sizes. The pupil of the eye affected by the cataract will be nonreactive to light. Remember to always consider the size of the pupils relative to each other in the context of the patient’s overall condition.

Eye Injuries Following Head Injury

Abnormalities in the appearance or function of the eyes often occur following a closed head injury. Any of the following eye findings should alert you to the possibility of a head injury:

- One pupil larger than the other (**FIGURE 29-26**)
- The eyes do not move together or they point in different directions (**dysconjugate gaze**)
- The eyes fail to follow the movement of your finger as instructed
- Bleeding under the conjunctiva, which obscures the sclera (white portion) of the eye
- Protrusion or bulging of one eye

FIGURE 29-26 Variation of pupil size may indicate a head injury.

© American Academy of Orthopaedic Surgeons.

Record any of these observations, along with the time that you make them. With an unresponsive patient, remember to keep the eyelids closed; drying of the ocular tissues can cause permanent injury and may result in blindness. Cover the lids with moist gauze, or hold them closed with clear tape for particularly long transports. Normal tears will then keep the tissues moist.

Blast Injuries

The signs and symptoms of blast injuries can range from severe pain and loss of vision to foreign bodies within the globe. Before responding to patients after the blast, first ensure the scene is safe.

How you manage a blast injury to the eye will depend on the severity of the injury. If a foreign body is embedded within the globe, then do not attempt to remove it. Use a clean cup or similar item to protect the area. If only one eye is injured, then follow local protocol, which may include covering the other eye to eliminate sympathetic motion. Patients who experience a sudden loss or decrease of vision will need verbal instructions on which actions are taking place around them. If the patient has severe swelling or a hematoma to the eyelid, then do not attempt to force the eyelid open to examine the eye because this action increases the pressure already present within the globe.

YOU are the Provider

Part 4

Finding the patient's bleeding to be venous in nature, you instruct your partner to apply mild pressure above and below the injury in an attempt to control bleeding. Once the rate of bleeding has been controlled, you advise the fire department personnel that you believe it is safe to continue operations, ensuring they are cognizant of the potential for serious injury. After the patient has been freed from the implement, you place him on a long backboard in the lateral position with the right side down and the left side up to facilitate stabilization of the impaled object. You are unable to place a cervical collar on this patient, so instead you place a large amount of padding around his neck, and stress to the patient the importance of not moving his head. He acknowledges the seriousness of the situation and assures you he has no intention of moving anything.

Once the patient is secured and placed in the back of the ambulance, you reassess the security of the object and add a few more bulky dressings as a precaution. You inform your partner that you need a rapid, but very smooth transport to the trauma center. He tells you he understands and proceeds to the trauma center approximately 12 minutes away.

While you are en route, you establish two 18-gauge IV lines with normal saline at a to-keep-open (TKO) rate. You remember the patient stated he was getting increasingly short of breath and you ask him how he feels now. He replies that he feels better with the oxygen mask but is concerned about the piece of steel in his neck. You discuss the possible implications of his injury with him, and he appears calm. The remainder of your examination is unremarkable.

After you arrive at the trauma center and turn over care, you complete the patient care report while your partner readies the truck for the next call.

Recording Time: 23 Minutes

Respirations	18 breaths/min; clear bilaterally
Pulse	105 beats/min
Skin	Warm and dry
Blood pressure	124/76 mm Hg
Oxygen saturation (SpO₂)	95% with oxygen at 15 L/min via nonrebreathing mask
Pupils	PERRLA

7. What are some possible causes of this patient's initial shortness of breath?
8. If you do not have the tools to cut the object and free the patient, should you remove the object from his neck?

Contact Lenses and Artificial Eyes

Small, hard contact lenses usually are tinted, making them relatively easy to see. Large, soft contact lenses are clear and can be very difficult to see. In general, you should not attempt to remove either kind of lens from a patient. You should never attempt to remove a lens from an eye that has been—or may have been—injured, because manipulating the lens can aggravate the problem.

Words of Wisdom

The only time when contact lenses should be removed immediately in the field is in the case of a chemical burn of the eye. In this situation, the lens can trap the chemical and make irrigation more difficult.

If it is necessary to remove a hard contact lens, use a small suction cup, moistening the end with saline. To remove soft lenses, place one to two drops of saline in the eye, gently pinch the lens between your gloved thumb and index finger, and lift it off the surface of the eye. Place the contact lens in a container filled with sterile saline solution to prevent damage to the contact lens. Always inform the ED staff if a patient is wearing contact lenses.

Occasionally, you may find yourself caring for a patient who is wearing an eye prosthesis (an artificial eye). Many people are surprised to find that it can be difficult to distinguish a prosthesis from a natural eye. You should suspect an eye is artificial when it does not respond to light, does not move in concert with the opposite eye, or appears different from the opposite eye. If you think a patient may have an artificial eye but you are not sure, go ahead and ask about it. Although no harm will be done if you care for an artificial eye as you would a natural one, you need to clearly understand the patient's eye function.

Injuries of the Nose

Nosebleeds (epistaxis) are a common problem that can occur either spontaneously or as the result of trauma. The most common causes of nosebleeds are dry air and digital trauma (picking the nose with a finger). Nosebleeds are classified into two types, based on the area of the bleeding: anterior

and posterior. Anterior nosebleeds usually originate from the area of the septum and bleed fairly slowly; they are usually self-limited and resolve quickly. Posterior nosebleeds are usually more severe and often cause blood to drain into the patient's throat, leading to nausea and vomiting. Trauma to the face and skull that results in a **basilar skull fracture** will often cause the posterior wall of the nasal cavity to become unstable. Attempting to place a nasopharyngeal airway in a patient with a suspected basilar skull fracture or with facial injuries is relatively contraindicated in the presence of midface trauma. As always, know and follow your local protocols.

The nose often takes the brunt of deliberate physical assaults and car crashes. Blunt injuries to the nose caused by a fist or a dashboard may be associated with fractures and soft-tissue injuries of the face, head injuries, and/or injuries to the cervical spine. Penetrating injuries to the nose can involve many mechanisms (eg, when air guns and BB pellets are fired from a close range, resulting in pellets lodging in the nasal septum and sinuses). Another type of penetrating injury to the nose is a self-inflicted one that occurs when a person attempts to insert a foreign body into the nose, such as a pencil.

When you are assessing injuries involving the nose, it helps to picture the inside of the nose itself (**FIGURE 29-27**). The nasal cavity is divided into two sections or chambers by the nasal septum, which is made of cartilage. Each nasal chamber contains layers of bone called the **turbinates**, which are covered with a moist lining. Both chambers have a superior turbinate, a middle turbinate, and an inferior turbinate. As a person breathes, air moves through the nasal chambers and is humidified, warmed, and filtered as it passes over the turbinates. Directly above the nose are the frontal sinuses and, on either side, the orbit of the eye. In patients with severe injury, there may also be injury to the cervical spine. In addition, CSF may escape down through the nose (or ears) following a fracture at the base of the skull.

Epistaxis following facial trauma can be severe and is most effectively controlled by applying direct pressure to the nares. If the patient is responsive and spinal injury is not suspected, then instruct the patient to sit up and lean forward as you pinch the nares together or press on the upper gums³ (**FIGURE 29-28**). Unresponsive patients should be positioned on their sides, unless contraindicated

FIGURE 29-27 The nose has two chambers, divided by the septum. Each chamber is composed of layers of bone called turbinates. Above the nose are the frontal sinuses and, on either side, the orbit of the eye.

© Jones & Bartlett Learning.

by a spinal injury. Proper positioning of the patient with epistaxis is important to prevent blood from draining into the throat and compromising the airway either by occlusion or by vomiting and then aspirating gastric contents.

You can control bleeding from abrasions and lacerations to the nose by applying a sterile dressing. If the patient is bleeding heavily from the nose, then you should suspect significant trauma and you must consider a cervical spine injury. The patient should not be moved if the airway can be managed in the patient's present position.

Although facial lacerations and avulsions can contribute to hemorrhagic shock, they are rarely the sole cause of this condition in adults. However, severe epistaxis can result in significant blood loss. To manage this problem, carefully assess the patient for signs of hemorrhagic shock and administer crystalloid fluid boluses intravenously as needed to maintain adequate perfusion.

Injuries of the Ear

Injuries to the ear may be isolated, or they may occur in conjunction with other injuries to the head or

A

B

FIGURE 29-28 Control bleeding from the nose by one of the following methods: either pinch the nostrils together (**A**) or apply pressure on the upper gums, beneath the nose, with gloved fingers and gauze (**B**).

© Jones & Bartlett Learning.

face. Although isolated ear injuries are typically not life threatening, they can result in sensory impairment and permanent disfigurement.

Ears usually do not bleed very much. If local pressure does not control the bleeding, then you can apply a roller dressing (**FIGURE 29-29**). First, however, you should place a soft, padded dressing between the back of the ear and the scalp because bandaging the ear against the tender underlying scalp can be extremely painful for the patient. If blood or CSF drainage is noted, then apply a loose dressing over the ear, taking care *not* to stop the flow, and assess the patient for other signs of a basilar skull fracture.

If the pinna is partially avulsed, then carefully realign the ear into position and gently bandage it with sufficient padding that has been slightly

A

B

FIGURE 29-29 **A.** A major laceration of the ear. **B.** Proper treatment includes use of a soft, sterile pad behind the ear, between it and the scalp. Then wrap a roller gauze dressing around the head to include the entire ear.

A: © American Academy of Orthopaedic Surgeons; B: © Jones & Bartlett Learning. Courtesy of MIEMSS.

moistened with normal saline. If the pinna is completely avulsed, attempt to retrieve the avulsed part, if possible, for reimplantation at the hospital. If the detached part of the ear is recovered, then treat it as any other amputation; wrap it in saline-moistened gauze, place it in a plastic bag, and place the bag in ice water. Never place an amputated part directly on ice.

Do not remove an impaled object from the ear. Instead, stabilize the object and cover the ear to prevent gross movement and minimize the risk of contamination of the inner ear.

The external auditory canal is a favorite place for children to place foreign bodies such as peanuts or candy. All such items should be removed by a physician in the ED. Never try to manipulate the foreign body because you may press it farther into

the auditory canal and cause permanent damage to (perforation of) the tympanic membrane.

Perforation of the tympanic membrane (ruptured eardrum) can also result from direct blows and pressure-related injuries, such as blast injuries resulting from an explosion, or diving-related injuries that result in barotrauma to the ear. Signs and symptoms of a perforated tympanic membrane include loss of hearing and blood drainage from the ear (hemorrhagic otorrhea). Although the injury is extremely painful for the patient, the tympanic membrane typically heals spontaneously and without complication. Nevertheless, a careful assessment should be performed to detect and treat other injuries, some of which may be life threatening.

Facial Fractures

Fractures of the facial bones typically result from blunt impact. For example, the patient's head may collide with a steering wheel or windshield in an automobile crash or be hit by a baseball bat or pipe in an assault. If the patient sustained a direct blow to the mouth or nose, then maintain a high index of suspicion for a facial fracture. Other clues to the possibility of fracture include bleeding in the mouth, inability to swallow or talk, absent or loose teeth, and/or loose or movable bone fragments. Patients may also report that “it doesn't feel right” when they close their jaw, signaling an irregularity of bite.

Facial fractures alone are not acute emergencies unless there is serious bleeding; however, they are an indication of significant blunt force trauma applied to that region of the body. Serious bleeding from a facial fracture can be life threatening. In addition to the danger posed by external hemorrhage, blood clots may become lodged in the upper airway and cause an obstruction (**FIGURE 29-30**). Fractures around the face and mouth can also produce deformity and loose bone fragments. In most cases, plastic surgeons can repair the damage if the injuries are treated within 7 to 10 days of the injury. Ensure you remove and save avulsed teeth or free bone fragments from the mouth; it is often possible to reimplant them (**FIGURE 29-31**). Remove any loose dentures or dental bridges to protect against airway obstruction. The removal of dentures will affect the shape of the patient's jaw.

FIGURE 29-30 Bleeding following a crushing injury to the face can be life threatening because, in addition to the danger posed by external hemorrhage, blood clots in the airway can cause a complete obstruction.

© Charles Stewart, MD, EMDM MPH.

Another source of potential airway obstruction is swelling, which can be extreme within the first 24 hours after injury. If you notice swelling during assessment or at any time while the patient is in your care, then check for airway obstruction.

Oral and Dental Injuries

Oral and dental injuries are commonly associated with trauma to the face. Blunt mechanisms typically result from MVCs or direct blows to the mouth or chin. Penetrating mechanisms often take the form of gunshot wounds, lacerations, and punctures. Dental injuries can be traumatic to a patient. Not only is the injury itself traumatic, but the patient's permanent teeth may also be lost—affecting everything from eating to smiling. Keep this in mind when providing care.

The primary risk associated with oral and dental injuries is airway compromise from oropharyngeal bleeding, occlusion by a displaced dental appliance such as a bridge or partial plate, and possibly aspiration of avulsed or fractured teeth. Any patient with significant facial trauma should be carefully assessed for injuries to the mouth and teeth. Suction the oropharynx as needed, and remove fractured tooth fragments to prevent airway compromise. Apply spinal immobilization as dictated by the MOI (a patient with significant impact to the face or mouth should be considered to have cervical spine trauma until proven otherwise).

A

B

FIGURE 29-31 **A.** Save any lost teeth or bone fragments following an injury to the mouth. **B.** Even with traumatic loss of a tooth, the possibility of successful reimplantation is very good.

© American Academy of Orthopaedic Surgeons.

Bleeding will occur whenever a tooth is violently displaced out of its socket; you should apply direct pressure to stop the bleeding. Patients may also swallow blood from lacerations inside the mouth, so the bleeding may not be grossly evident. Because blood irritates the gastric lining, the risks of vomiting and aspiration are significant when it is swallowed. For severe oropharyngeal bleeding in patients with inadequate ventilation, suction the airway for 15 seconds and provide ventilatory assistance for 2 minutes; continue this alternating pattern of suctioning and ventilating until the airway is cleared of blood or secured with an endotracheal tube by paramedic backup. You can also turn the backboard to the side to help clear the airway. Monitor the pulse oximeter during this process to ensure the patient does not become hypoxic.

Street Smarts

Alert patients who have oral trauma may prefer to hold the suction catheter themselves. Allowing the patient to do so can lessen their anxiety and give them a sense of control in a situation where they feel very vulnerable.

Leave impaled objects in the face in place and appropriately stabilize them, unless they pose a threat to the airway (such as an object impaled through the cheek). When you remove an object from the cheek, carefully remove it, preferably from the same side that the object entered. Next, pack the inside of the patient's cheek with sterile gauze and apply counterpressure with a dressing and bandage firmly secured over the outside of the wound. If profuse bleeding continues, then position the patient on the side—while maintaining stabilization of the cervical spine—to facilitate drainage of secretions from the mouth; suction the airway as needed.

When dealing with an avulsed tooth, handle it by its crown and not by the root. Gently rinse the tooth with a sterile saline solution or water; do not use soap or chemicals, and do not scrub the tooth. When transporting the patient, bring along the tooth, place it in a special tooth storage solution, if available in your supplies, or in cold milk or sterile saline.^{4,5} Do not allow the tooth to dry. Alternatively, your agency may use commercially available kits for this purpose. Be familiar with how the kit is used before you encounter a patient with dental trauma. Notify the receiving facility about the avulsed tooth, because reimplantation is recommended within 20 minutes to 1 hour after the trauma.

Injuries of the Neck

The neck contains many structures that are vulnerable to injury by blunt trauma, such as from a steering wheel in a car crash, or by penetrating injury, such as a stab or gunshot wound. These structures include the upper airway, the esophagus, the carotid arteries and jugular veins, the thyroid cartilage (ie, Adam's apple), the cricoid cartilage, and the upper part of the trachea.

Any injury to the neck is serious and should be considered life threatening until proven otherwise in the ED. Blunt and penetrating mechanisms can

damage both the soft tissues of the anterior part of the neck and its associated structures. In both cases, you must be alert for the possibility of cervical spine injury and airway compromise.

Blunt Injuries

Any crushing injury of the upper part of the neck is likely to involve the larynx or trachea. Examples include a collision with a steering wheel, an attempted suicide by hanging, and a clothesline injury sustained while riding a bicycle. Once the cartilages of the upper airway and larynx are fractured, they do not spring back to their normal position. This type of fracture can lead to loss of voice, difficulty swallowing, severe and sometimes fatal airway obstruction, and leakage of air into the soft tissues of the neck (**FIGURE 29-32**). The presence of air in the soft tissues produces a characteristic crackling sensation called **subcutaneous emphysema**. If you feel this sensation when you palpate the neck, you should maintain the airway as best you can and provide immediate transport. Be aware that complete airway obstruction can develop very rapidly in these patients as a result of swelling or bleeding into the underlying tissues. It may be very difficult to manage the airway in patients with these injuries; therefore, paramedic support either by air or during an intercept may be necessary. Some patients will require a surgical airway at the hospital. An incident involving an injury to the throat may also have caused a cervical spinal injury; therefore, spinal immobilization may be needed.

FIGURE 29-32 Fractures of the larynx or trachea can cause air to leak from the airway into the subcutaneous tissues. The presence of air in the soft tissues produces a crackling sensation called subcutaneous emphysema.

© American Academy of Orthopaedic Surgeons.

Penetrating Injuries

The lacerations or puncture wounds produced by penetrating injuries may be superficial and involve only the fascia or fatty tissues of the neck, or they may be deep and involve injury to the larynx, trachea, esophagus, nerves, or major blood vessels. The primary threats from penetrating neck trauma are massive hemorrhage from major blood vessel disruption and airway compromise secondary to soft-tissue swelling or direct damage to the larynx or trachea.

Penetrating injuries to the neck can cause profuse bleeding from laceration of the carotid arteries or the jugular veins (**FIGURE 29-33**). Injuries to the carotid and jugular vessels in the neck can cause the body to bleed out, a phenomenon also known as **exsanguination**.

A special danger associated with open neck injuries is the possibility of a fatal **air embolism**. If the jugular veins of the neck are exposed to the environment, then the veins may entrain (suck) air into the vessel and occlude the flow of blood into the lungs. A large amount of air entrained into the right atrium and right ventricle of the heart can lead to cardiac arrest. As such, immediately seal open neck wounds with an occlusive dressing. Use caution to avoid constricting the vessels and structures of the neck. Also, be alert for swelling and expanding hematomas because these conditions can turn the occlusive dressing into a constricting band.

FIGURE 29-33 Penetrating injuries to the neck can result in profuse bleeding if a carotid artery or jugular vein is damaged.

© American Academy of Orthopaedic Surgeons.

Direct pressure over the bleeding site will control most neck bleeding. Follow the steps in **SKILL DRILL 29-3**. You might find it necessary to apply pressure above *and* below the penetrating wound to control life-threatening bleeding from the carotid artery (above) and the jugular vein (below). You may also need to treat the patient for shock.

Impaled objects in the neck can present several life-threatening conditions for the patient—namely, injury to major blood vessels with massive hemorrhage; damage to the larynx, trachea, or esophagus; or injury to the cervical spine. Do not remove impaled objects. Instead, stabilize the object in place and protect it from movement. The *only* exception is if the object is obstructing the airway or impeding your ability to effectively manage the airway.

If indicated, maintain cervical spine immobilization, and with the patient fully immobilized on a backboard, provide prompt transport. Ensure the airway remains open en route, and administer high-flow oxygen. Obtain vascular access en route.

Words of Wisdom

Do not circumferentially wrap bandages around the neck to secure the dressing in place when controlling bleeding from a neck injury (**FIGURE 29-34**). This practice is contraindicated and can be fatal if it impairs cerebral perfusion by occluding both carotid arteries or if it interferes with the patient's breathing. Monitor the patient's pulse for reflex bradycardia, which indicates parasympathetic nervous stimulation due to excessive pressure on the carotid artery.

Laryngeal Injuries

Blunt force trauma to the larynx can occur when an unrestrained driver strikes the steering wheel or when a snowmobile rider or off-road biker strikes a clothesline or a fixed wire strung across a property line. The larynx becomes crushed against the cervical spine, resulting in soft-tissue injury, fractures, and/or separation of the fascia that connects the thyroid and cricoid cartilages. These strangulation injuries can also be found in intentional or unintentional hangings. Whenever injury to the larynx is a possibility, you should suspect a possible cervical spine injury.

Skill Drill 29-3 Controlling Bleeding From a Neck Injury

Step 1

Apply direct pressure to the bleeding site using a gloved fingertip if necessary to control bleeding.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 2

Apply a sterile occlusive dressing to ensure air does not enter a vein or artery. Secure the dressing in place with roller gauze, adding more dressings if needed.

FIGURE 29-34 Cover open neck wounds with an occlusive dressing, and apply manual pressure to control bleeding. Secure the dressing in place by wrapping roller gauze around and under the patient's shoulder in a figure-8 pattern.

Courtesy of Rhonda Hunt.

Open injuries to the larynx can occur as a result of a stabbing or penetration by a similar object. Do not remove penetrating and impaled objects unless they interfere with cardiopulmonary resuscitation.

Stabilize all impaled objects if they are not obstructing the airway. (See Chapter 28, *Soft-Tissue Injuries*.)

Many injuries to the larynx, trachea, and esophagus are occult. They are not as obvious and dramatic as penetrating neck injuries, so you may easily overlook them. Therefore, maintain a high index of suspicion and perform a careful assessment of *any* patient with blunt trauma to the anterior part of the neck.

Significant injuries to the larynx pose an immediate risk of airway compromise because of disruption of the normal passage of air, soft-tissue swelling, or aspiration of blood. The signs and symptoms of larynx injuries include respiratory distress, hoarseness, pain, difficulty swallowing (**dysphagia**), coughing up blood (**hemoptysis**), cyanosis, pale skin, sputum in the wound, subcutaneous emphysema, bruising on the neck, structural irregularity, hematoma, or bleeding. In addition, esophageal perforation can result in **mediastinitis**, an inflammation of the mediastinum that is often due to leakage of gastric contents into the thoracic cavity. Mediastinitis has a very high mortality rate, particularly without rapid surgical treatment. Whenever injury to the anterior part of the neck (specifically the larynx)

is recognized or suspected, it is prudent to ask the patient to refrain from speaking to allow the vocal cords to rest and recuperate. This will require you to ask questions that can be simply answered with a yes or no. Alternatively, you may ask the patient to write down the answers to your questions. Remember, if the larynx is injured, the incidence of cervical spine injury is relatively high; therefore, the patient should avoid shaking the head when responding.

Your primary focus when caring for a patient is always to treat the most rapidly fatal injuries. Because death following trauma to the anterior part of the neck is usually the result of airway compromise or massive bleeding, your priorities of care must be to aggressively manage the airway and control any external bleeding.

To manage a laryngeal and/or tracheal injury, provide oxygenation and ventilation, preferably with careful two-person bag-mask ventilation. Patients with injuries to the anterior part of the neck may experience concomitant maxillofacial fractures, which can make bag-mask ventilation difficult (usually because of an inadequate mask-to-face seal). Apply a cervical collar, but avoid using rigid collars because they may cause further damage to the soft tissues. Be alert to the need for frequent suctioning. Do not delay transport, because immediate surgical intervention may be the best treatment option. Call for paramedic rendezvous for advanced airway management, especially if the patient is apneic. If signs of shock are present, keep the patient warm. Establish vascular access with at least one large-bore IV line while en route to the hospital, if possible, or on scene if indicated. Infuse an isotonic crystalloid solution (such as lactated Ringer solution or normal saline) as needed to maintain adequate perfusion.

Muscular Injuries

The neck, because of its relative exposure to forces both directly applied and referred, is subject to injury that does not necessarily result in specific bony injury such as fracture or dislocation. Most of these nonpenetrating injuries are typically classified as sprains and strains.

A **sprain** is a stretching or tearing of ligaments, the tough bands of fibrous tissue that connect one bone to another. In response to strains in the neck, the muscles contract as they attempt to support the

neck. It is believed that this response is the result of injury to the facet joint. This injury can be difficult, if not impossible, for you to identify in the prehospital setting. As a result, maintain a high index of suspicion for cervical involvement and provide cervical spine stabilization.

A **strain** is a stretching or tearing of muscle or tendon. The most common form of cervical strain is often called **whiplash**. Whiplash can be difficult to differentiate from an unstable spine fracture or dislocation. Although whiplash is rarely life threatening, morbidity can occasionally develop in the form of persistent and chronic cervical pain, with some patients experiencing prolonged spasms and exacerbation.

Because it is difficult for you to evaluate complaints of neck pain, it is recommended that you transport patients to the ED for radiologic studies. Conduct a visual inspection for signs of soft-tissue injury, which may indicate muscular and bony involvement. If the patient is symptomatic and has pain (either with or without movement and palpation), then provide spinal immobilization.

If you suspect musculoskeletal injury to the neck, then address any airway, ventilation, and oxygenation considerations and ensure there is no major circulatory compromise. Prehospital management should focus on preventing further injury by restricting range of motion. This typically involves applying a cervical collar and placing the patient on a long backboard, scoop stretcher, or vacuum mattress, if indicated. In critical patients, it may be necessary to perform these tasks simultaneously. Whether you are applying a long backboard, scoop stretcher, or vacuum mattress, as in all splinting procedures, it is essential to check distal pulse and sensory and motor function before and after the full-body splint is applied and to document those findings in your patient care report. Regardless of MOI, patients reporting neck pain should be evaluated for occult injuries and prevention of long-term consequences.

Injury Prevention

Because face and neck injuries can be life altering and permanent, there have been many medical improvements and advancements in how these areas of the body are protected. This is especially true in the area of organized sporting events such as

contact sports and other types of sports. Helmets, face shields, mouth guards, and safety eyewear help to prevent injury during activities in which the risk of being hit with objects that are in motion is proportionately high. There have also been many

advances in motor vehicle safety. Better occupant safety restraints and airbags help to prevent contact with the interior of the vehicle, and improvements to the headrests, if they are used properly, reduce the number of neck strains.

YOU are the Provider SUMMARY

1. On the basis of the information provided, what are some possible injuries you may encounter?

Penetrating injuries to the neck can cause profuse bleeding from laceration of the great vessels in the neck—the carotid arteries or the jugular veins. Injuries to the carotid and jugular vessels in the neck can cause the body to bleed out, also known as exsanguination. There is also a potential for cervical spine injury, as well as tracheal injury.

2. What is the best way to remove the piece of metal from the machinery?

There is no best way to remove this piece of metal from the machinery, and each situation is unique. If you are not familiar with different extrication methods that may be used to free the patient, then decisions made regarding extrication are best left to subject matter experts, after discussing the matter with emergency medical service providers and determining the potential risks and precautions that may need to be taken. Regardless of the method used, seek to minimize movement of the object and use methods to decrease the amount of heat generated.

3. How would you secure the tension rod to the patient?

This tension rod should be secured with large amounts of bulky dressing. Bulky dressings can be applied around the object in an attempt to prevent the rod from moving.

4. Why should you be concerned about air entering the wound?

If a vein has been punctured, then air may be sucked through it to the heart, causing an air embolism. The entry of a large amount of air in the right atrium and right ventricle of the heart can lead to cardiac arrest. An occlusive dressing should be applied over the entrance wound to prevent the introduction of air into the circulation.

5. How can you control bleeding from a neck wound?

Controlling bleeding from a neck wound may be difficult because direct pressure may compress arterial

blood flow, creating a situation that can diminish the amount of oxygen delivered to the brain. Pressure can be applied above and below the wound, depending on whether the bleeding is arterial or venous, in an attempt to slow the bleeding, but always be cognizant of the potential for diminished blood flow to the brain. Also, ensure you use an occlusive dressing for any neck wound.

6. Will this patient need to be immobilized with a cervical collar before transport? How will you immobilize his head?

This patient has an isolated puncture injury to his neck. There is no mechanism consistent with injury to other parts of his spine. As long as he is awake and alert and able to report no back or low lumbar pain or tenderness, and as long as he is reliable based on no evidence of intoxication, traditional spinal immobilization with a backboard and collar can and should be avoided in favor of positioning in a way that facilitates stabilization of the impaled object, typically the lateral recumbent position on a backboard. In addition, with an object protruding from his neck, it may be difficult, if not impossible, to apply a cervical collar. If this is the case, manual stabilization can be maintained until arrival at the trauma center, or improvised materials may be applied to create a makeshift collar. Any neck movement could result in massive injury. Immobilize the patient to prevent further soft-tissue damage from the rod and to protect the neck from further injury. Keep suction readily available to assist in airway management.

7. What are some possible causes of this patient's initial shortness of breath?

There may be many different causes for this patient's shortness of breath. It could be a result of anxiety, shock, or potentially a fractured trachea. Signs and symptoms of a fractured trachea include respiratory distress, hoarseness, pain, difficulty swallowing (dysphagia), hemoptysis, cyanosis, pale skin, sputum in the wound, subcutaneous emphysema, bruising on the neck, structural irregularity, hematoma, and bleeding. Regardless of the cause, administer

YOU are the Provider **SUMMARY** *continued*

high-flow oxygen to the patient until it has been determined oxygen is no longer needed.

8. If you do not have the tools to cut the object and free the patient, should you remove the object from his neck?

If you do not have the necessary equipment or training to free the patient, extrication is best left to

subject matter experts, typically, the responding fire department personnel. In the event that you do not have that option, object removal is a last resort. In that case, it should be done quickly and the wound should be rapidly covered with an occlusive dressing and direct pressure applied.

Narrative

EMS dispatched to a residential farm for an unknown machinery accident. En route, dispatch updated information that the patient is male, with an unknown object impaled in his neck; fire department responding as well. On arrival, patient found standing with arms wrapped around farm implement, with approximately a 3-foot piece of 0.5-inch-diameter metal impaled in left side of neck. Distal end still connected to implement. Patient presents as alert and oriented × 4; ABCs intact. States he was attempting to free an obstruction when tension rod "snapped" and impaled him in the neck. Complaining of increasing shortness of breath. Administered oxygen at 15 L/min via NRM with cervical spine being held by firefighter. Occlusive dressing placed around rod, with copious amounts of bulky dressings applied for stabilization. Firefighters used hacksaw to cut rod, leaving approximately 10 inches protruding from neck. Noted an increase in visible bleeding from wound; direct pressure applied to superior and inferior vein, with bleeding being controlled. Once tension rod separated from implement, patient placed in lateral position on backboard to facilitate stabilization of rod. Patient had strong pulse, normal motor activity, and normal circulation in all 4 extremities. Unable to apply cervical collar owing to nature of injury; head immobilized with towel rolls and secured to backboard. Patient placed in back of ambulance and transported on emergency basis to trauma center. En route, 18-gauge IV line established in right AC and left AC with NS TKO in both. Patient states that he is breathing better with oxygen, and other than being scared, he has no other complaints. Physical examination is unremarkable. On arrival at trauma center, care and report given to staff without incident.

End of report

Prep Kit

Ready for Review

- The skull is divided into two large bony structures that protect the brain: the cranium and the face.
- Soft-tissue injuries and fractures of the bones of the face and neck are common and vary in severity.
- Airway compromise may be caused by heavy bleeding into the airway, swelling in and around the structures of the airway located in the face and neck, and injuries to the central nervous system that interfere with normal respiration.
- Trauma to the face can range from a broken nose to more severe injuries, including massive soft-tissue trauma, maxillofacial fractures, oral or dental trauma, and eye injuries.
- In face and neck injuries, your priorities are to prevent further injury to the cervical spine, manage the patient's airway and breathing, and control bleeding. Do not let soft-tissue injuries distract you from life threats that may not be readily apparent.
- Always check for bleeding inside the mouth, as it may produce an airway obstruction. In the event of profuse bleeding within the mouth, position the patient on the side to facilitate drainage of secretions from the mouth; suction the airway as needed.
- Provide rapid transport for a patient with any of the following signs and symptoms: hypoperfusion, significant MOI, poor general impression, altered level of consciousness, abnormal vital signs, dyspnea, severe pain, or an isolated eye injury.
- To control heavy bleeding from soft-tissue injuries to the face, use direct pressure with a dry, sterile dressing. If brain tissue is exposed, then use a moist, sterile dressing.
- Save avulsed pieces of skin and tissue, and transport them with the patient for possible reattachment at the hospital.
- Maintain a high index of suspicion for patients with unequal pupils—this sign may indicate an illness or an injury to the brain. However, some people are born with one pupil larger than the other, so ask the patient whether the pupils are normally unequal.
- Foreign bodies on the surface of the eye should be irrigated gently with normal saline solution. Always flush from the region of the eye closest to the nose toward the outside, away from the midline.
- If a foreign body is stuck on the underside of the eyelid, then gently remove it with a cotton-tipped applicator. Never remove foreign bodies that are stuck to the cornea.
- Chemicals, heat, and light rays can all cause burn injury to the eyes, resulting in permanent damage. Treat chemical burns of the eye using gentle irrigation. Cover thermal eye burns and eye burns from light and transport the patient.
- If there is a laceration of the globe itself, then apply a moist, sterile dressing, and cover the injured eye with a protective metal eye shield, cup, or sterile dressing.
- Epistaxis following facial trauma can be severe. To effectively control it, apply direct pressure to the nares or apply pressure on the upper gums. Be alert to clear fluid draining from the ears or nose, as it may indicate a basilar skull fracture.
- When treating an ear injury, if local pressure does not control the bleeding, use a roller

dressing. In the case of an ear avulsion, wrap the avulsed part in a moist, sterile dressing and put it in a labeled plastic bag, keep it cool, and transport it to the hospital with the patient. Never try to manipulate a foreign body that is in the ear canal.

- With dental injuries, apply direct pressure to stop the bleeding, keep the airway patent, and suction if needed. Cracked or loose teeth are possible airway obstructions. If a tooth is avulsed, then transport it with the patient, in an appropriate solution; do not let it become dry.
- If an object is impaled in the patient's cheek and bleeding from the wound is compromising the patient's airway, consider removing the impaled object, if possible. Apply direct pressure on the inside and outside of the cheek.
- Blunt and penetrating trauma to the neck can produce life-threatening injuries. Palpate the neck for signs of subcutaneous emphysema. In patients with this sign, complete airway obstruction may develop in minutes.
- If bleeding is present from a penetrating injury, then apply direct pressure over the site to control most forms of bleeding.
- Be alert to the possibility of an air embolism from an open neck injury. Place an occlusive dressing over the site, and provide direct pressure.
- Blunt force trauma can crush the larynx, resulting in soft-tissue injury, fractures, and potential spinal injury. Signs and symptoms of larynx injuries include hoarseness, pain, difficulty swallowing (dysphagia), hemoptysis, cyanosis, sputum in the wound, subcutaneous emphysema, and structural irregularity. Aggressively manage the airway, and call for paramedic rendezvous.
- If you recognize or suspect injury to the anterior part of the neck (specifically the larynx), then ask the patient to refrain from speaking to allow the vocal cords to rest and recuperate.
- In the case of a complaint of neck pain, maintain spinal immobilization and transport the patient to the ED for radiologic studies.

Vital Vocabulary

air embolism The presence of air in the venous circulation, which forms a gas bubble that can block the outflow of blood from the right ventricle to the lung; can lead to cardiac arrest, shock, or other life-threatening complications.

anisocoria Uneven pupil size; can be naturally occurring, but also can be a sign of pathology.

aqueous humor The clear, watery fluid in the anterior chamber of the globe (eyeball).

basilar skull fracture An injury that usually occurs following diffuse impact to the head (such as in falls, motor vehicle crashes); generally results

from extension of a linear fracture to the base of the skull and can be difficult to diagnose with a radiograph, requiring computed tomography.

blowout fracture A fracture of the orbit or of the bones that support the floor of the orbit.

conjunctiva The delicate membrane that lines the eyelids and covers the anterior exposed surface of the eye.

conjunctivitis Inflammation of the conjunctiva.

craniofacial disjunction A Le Fort III fracture; involves a fracture of all of the midfacial bones,

thereby separating the entire midface from the cranium.

diplopia Double vision.

dysconjugate gaze Paralysis of gaze or lack of coordination between the movements of the two eyes.

dysphagia Pain, discomfort, or difficulty in swallowing.

epistaxis Nosebleed.

exsanguination Severe, possibly life-threatening loss of blood.

globe The eyeball.

hemoptysis The spitting or coughing up of blood.

hyoid bone A bone at the base of the tongue that supports the tongue and its muscles.

hyphema Bleeding into the anterior chamber of the eye; results from direct ocular trauma.

lacrimal glands The glands that produce fluids to keep the eye moist; also called tear glands.

Le Fort fractures Maxillary fractures that are classified into three categories based on their anatomic location.

malocclusion Misalignment of the teeth.

mediastinitis Inflammation of the mediastinum that often results when gastric contents leak into the thoracic cavity after esophageal perforation.

oculomotor nerve The cranial nerve (III) that innervates most of the muscles that cause motion of the eyeballs and upper eyelid.

optic nerve Either of the second cranial nerves that enter the eyeball posteriorly, through the optic foramen, which transmit visual information to the brain.

pinna The external, visible part of the ear.

pupil The circular opening in the middle of the iris that admits light to the back of the eye.

retinal detachment Separation of the retina from its attachments at the back of the eye.

sclera The tough, fibrous, white portion of the eye that protects the more delicate inner structures.

sprain A joint injury involving damage to supporting ligaments (stretching or tearing) and partial or temporary dislocation of bone ends.

sternocleidomastoid muscles The muscles on either side of the neck that allow movement of the head.

strain Stretching or tearing of a muscle or tendon; also called a muscle pull.

subcutaneous emphysema A characteristic crackling sensation felt on palpation of the skin, caused by the presence of air in soft tissues.

sympathetic eye movement The movement of both eyes in unison.

temporomandibular joint The joint where the mandible meets with the temporal bone of the cranium just in front of each ear.

turbinates Bony shelves that extend from the lateral walls of the nose into the nasal passageway; increase the surface area of the nasal mucosa, improving filtration, warming, and humidification of inhaled air.

vitreous humor A jellylike substance found in the posterior compartment of the eye between the lens and the retina.

whiplash An injury to the neck in which hyperextension occurs as a result of the head moving abruptly forward or backward; can be difficult to differentiate from injuries that involve cervical bony structures and the spine.

Nervous System Trauma

Pathophysiology, assessment, and management of

- Traumatic brain injury (pp 1408–1409)
- Spinal cord injury (pp 1417–1419)

KNOWLEDGE OBJECTIVES

1. List the major bones of the skull and spinal column and their related structures, and describe their functions as related to the nervous system. (pp 1398–1400)
2. Review the anatomy and physiology of the nervous system, including its divisions into the central nervous system (CNS) and peripheral nervous system and the structures and functions of each. (pp 1397, 1400–1405)
3. Describe the regions of the brain, including the cerebrum, diencephalon, brainstem, and cerebellum, and their functions. (pp 1400–1402)
4. Discuss age-related variations that are required when providing emergency care to a pediatric patient who has a suspected head or spinal injury. (p 1405)
5. List the mechanisms of injury that cause a high index of suspicion for the possibility of a head or spinal injury. (pp 1405, 1415)
6. Discuss the different types of head injuries, their potential mechanism of injury (MOI), and general signs and symptoms of a head injury that the advanced emergency medical technician (AEMT) should consider when performing a patient assessment. (pp 1405–1406)
7. Distinguish between the signs and symptoms of head injury and those of traumatic brain injury. (p 1406)

8. Define traumatic brain injury (TBI) and explain the difference between a primary (direct) injury and a secondary (indirect) injury, providing examples of possible mechanisms of injury that may cause each one. (pp 1408–1409)
9. Discuss the different types of brain injuries and their corresponding signs and symptoms, including increased intracranial pressure (ICP), concussion, contusion, and injuries caused by medical conditions. (pp 1405–1406, 1409–1414)
10. Discuss the different types of injuries that may damage the cervical, thoracic, or lumbar spine, providing examples of possible mechanisms of injury that may cause each one. (pp 1417–1418)
11. Describe the steps in the patient assessment process for a person who has a suspected head or spinal injury, including specific variations that may be required as related to the type of injury. (pp 1419–1421, 1424–1427)
12. Discuss when it would be appropriate to establish intravenous access in a patient with a head or spinal injury, including the importance of judicious fluid administration. (p 1428)
13. Describe the process of providing emergency medical care to a patient with a head injury, including the four general principles designed to protect and maintain the critical functions of the CNS. (pp 1428–1429)
14. Describe the process of providing emergency medical care to a patient with a spinal injury, including the implications of not properly caring for patients with injuries of this nature, the steps for performing manual in-line stabilization, implications for sizing and using a cervical spine immobilization device, and key symptoms that contraindicate in-line stabilization. (pp 1430–1433)
15. Describe the process of preparing patients who have suspected head or spinal injuries for transport, including the use and functions of a long backboard, short backboard, and other short spinal extrication devices to immobilize the patient's cervical and thoracic spine. (pp 1432–1447)
16. Explain the different circumstances in which a helmet should be either left on or taken off a patient with a possible head or spinal injury, and then list the steps AEMTs must follow to remove a helmet, including the alternate method for removing a football helmet. (pp 1448–1451)

SKILLS OBJECTIVES

1. Demonstrate how to perform a jaw-thrust maneuver on a patient with a suspected spinal injury. (p 1422)
2. Demonstrate how to perform manual in-line stabilization on a patient with a suspected spinal injury. (p 1431, Skill Drill 30-1)
3. Demonstrate how to apply a cervical collar to a patient with a suspected spinal injury. (pp 1432–1433, Skill Drill 30-2)
4. Demonstrate how to immobilize a patient with a suspected spinal injury to a long backboard. (pp 1436–1439, Skill Drill 30-3)
5. Demonstrate how to immobilize a patient with a suspected spinal injury to a scoop stretcher. (pp 1440–1441, Skill Drill 30-4)
6. Demonstrate how to immobilize a patient with a suspected spinal injury to a vacuum mattress. (pp 1442–1444, Skill Drill 30-5)
7. Demonstrate how to immobilize a patient with a suspected spinal injury who was found in a sitting position. (pp 1445–1447, Skill Drill 30-6)
8. Demonstrate how to immobilize a patient with a suspected spinal injury to a short backboard. (pp 1445–1447)
9. Demonstrate how to remove a helmet from a patient with a suspected head or spinal injury. (pp 1449–1450, Skill Drill 30-7)
10. Demonstrate the alternate method for removal of a helmet from a patient with a suspected head or spinal injury. (p 1451)

Introduction

The nervous system is a complex network of nerve cells that enables all parts of the body to function. It includes the brain, spinal cord, and peripheral nervous system, which contains several billion nerve fibers that carry information to and from all parts of the body. Because the nervous system is so vital, it is well protected. The brain lies within the skull, and the spinal cord is inside the bony spinal canal. Despite this protection, serious blows can damage the nervous system.

Terminology related to head trauma includes the following:

- **Head trauma** refers to both head injuries and traumatic brain injuries.
- **Head injury** is traumatic injury to the head that may result in injury to the scalp, head, or skull, but not including the face. The terms *head injury* and *traumatic brain injury* are frequently used interchangeably. For the purposes of this chapter, however, the term *head injury* will be used to describe injuries to the scalp or skull but not the brain or face.
- **Traumatic brain injury (TBI)** refers to an injury to the brain caused by an external force that may or may not result in physical, emotional, social, and vocational consequences.

These injuries, as well as spinal cord injury (SCI), will be discussed in this chapter. SCI is one of the most devastating injuries encountered by prehospital providers. TBI is a substantial cause of death and disability and is responsible for about 30% of trauma-related deaths each year.^{1,2} In 2014, TBI resulted in approximately 2.9 million visits to emergency departments (EDs), was diagnosed in

288,000 hospitalizations, and contributed to 56,800 deaths.²

This chapter first briefly reviews the anatomy and function of the central and peripheral nervous systems and of the skeletal system, information that you will need to make an accurate assessment of injuries to these systems. It then discusses specific head and spinal injuries, including signs, symptoms, and treatment. Extrication of patients with possible spinal injuries and removal of helmets are also described.

Anatomy and Physiology Review

The nervous system is divided into two anatomic parts: the central nervous system and the peripheral nervous system (**FIGURE 30-1**). The **central nervous system (CNS)** is composed of the brain and spinal cord. The **peripheral nervous system (PNS)** conducts sensory and motor impulses to and from the skin, muscles, and other organs to the spinal cord. The brain, located within the cranial cavity, is the largest component of the CNS.

The nervous system is responsible for the generation and control of two types of activities in general: voluntary and involuntary. **Voluntary activities** are the actions that we consciously perform, in which sensory input determines the specific muscular activity—for example, reaching across the table for a salt shaker or to pass a dish. **Involuntary activities** are the actions that are not under conscious control, such as breathing; in most instances, we inhale and exhale without consciously thinking about it. Many of our body's functions occur independent of thought, or involuntarily.

YOU are the Provider

Part 1

Your ambulance is dispatched to a local community swimming pool for a possible spinal injury. On arrival, you are met by the lifeguards who state the patient was running alongside the pool, slipped, and fell into the pool headfirst, striking his head on the bottom. They immediately took spinal precautions, placed the patient onto a floating backboard, and placed him alongside the pool. The patient has been in and out of responsiveness. As you begin your assessment, you find the patient alert and oriented, reporting no feeling in his arms and legs.

1. On the basis of the information provided, what are some possible injuries you may encounter?
2. Is this patient experiencing a primary or secondary brain injury?

FIGURE 30-1 The nervous system has two anatomic components: the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS is composed of the brain and the spinal cord. The PNS is composed of nerves that conduct sensory and motor impulses to and from the skin, muscles, and other organs to the spinal cord and, eventually, the brain.

© Jones & Bartlett Learning.

The Scalp

The scalp is composed of multiple layers. The subcutaneous tissue contains the major vessels supplying the scalp. These vessels are attached to the superficial fascia. Laceration or other compromise of these vessels can result in profuse hemorrhage. Although this hemorrhage is often not life threatening, it can distract you from other life-threatening injuries. At the same time, you cannot underestimate the potential for blood loss from scalp hemorrhage, particularly in patients who take blood thinners or have clotting disorders, to be rapidly lethal.

The Skull

The skull has two groups of bones: the cranium, which protects the brain, and the facial bones (**FIGURE 30-2**). The mandible (lower jaw), the only movable facial bone, is connected to the cranium by the temporomandibular joint in front of each ear. The cranium is composed of several thick bones that fuse together to form a shell above the eyes and ears that holds and protects the brain. It is occupied by 80% brain tissue, 10% blood supply, and 10% **cerebrospinal fluid (CSF)**. The brain connects to the spinal cord through a large

FIGURE 30-2 The skull has two large structures: the cranium and the face.

© Jones & Bartlett Learning.

opening at the base of the skull called the foramen magnum.

Four major bones make up the cranium. The most posterior portion of the cranium is called the occiput. On each side of the cranium, the lateral portions are called the temples or temporal regions. Between the temporal regions and the occiput lie

the parietal regions. The forehead is called the frontal region.

The face is composed of 14 bones. The upper, nonmoveable jawbones are called the maxillae; the cheekbones are called the zygomas; and the mandible is the lower, moveable portion of the jaw.

The orbit (eye socket) is made up of the frontal bone of the cranium and two facial bones: the maxilla and the zygoma. Together, these bones form a solid bony rim that protrudes around the eye to protect it. The nose mostly consists of flexible cartilage; in fact, only the proximal third of the nose is formed by bone with short bones forming the bridge of the nose.

The Spine

The spine consists of 33 irregular bones (vertebrae) articulating to form the vertebral column, which is the major structural component of the axial skeleton. These skeletal components are stabilized by ligaments, joint capsules, and muscle. Together these components support and protect neural elements while allowing for fluid movement and erect stature (**FIGURE 30-3**).

FIGURE 30-3 The spinal column is the body's central supporting system and consists of 33 bones divided into five sections. Each vertebra is numbered and referred to by a letter corresponding to the section of the spine where it is located plus its number. For example, the fifth thoracic vertebra is referred to as T5.

© Jones & Bartlett Learning.

Vertebrae are identified according to their location as cervical, thoracic, lumbar, sacral, or coccygeal. The **vertebral body**, the anterior weight-bearing structure, is made of bone that provides support and stability. The posterior portion of each vertebra forms a bony arch (**FIGURE 30-4**). From one vertebra to the next, the series of arches forms a tunnel running the length of the spine. This is the spinal canal, which encases and protects the spinal cord.

Each vertebra is separated and cushioned by **intervertebral disks** that limit bone wear and act as shock absorbers. As the body ages, these disks lose water content and become thinner, causing the height loss associated with aging. Stress on the vertebral column may cause a disk to herniate into the spinal canal, resulting in an injury to the spinal cord or a **nerve root injury** (**FIGURE 30-5**). Nerves can also be injured at the peripheral level (anywhere in the body outside of the spinal cord); this is called **peripheral nerve injury**.

The spinal column itself is almost entirely surrounded by muscles. However, you can palpate the posterior spinous process of the vertebra. In thin people, these lie just under the skin in the midline of the back. The most prominent and most easily palpable spinous process is at the seventh cervical vertebra at the base of the neck.

FIGURE 30-4 The spinal canal is formed by the vertebral body in the front (or anteriorly) and the bony arch in the back (or posteriorly).

Words of Wisdom

The lumbar spine is a common site of injury. Most of these injuries do not involve fracture or other structural disruption of the bony elements of the lumbar spine, but rather involve muscle spasm and do not threaten the integrity of the spinal cord or its nerve roots. Nonetheless, low back pain is a very common problem, as well as a major cause of impairment and disability.

The muscles, tendons, and ligaments that connect the vertebrae allow the spinal column a degree of flexion and extension, limited to an extent by the stabilization they must provide to the spinal column. The vertebral column can flex and extend substantially, allowing motion to occur without causing injury to the spinal cord. Flexion or extension beyond what the spine is capable of tolerating at any particular level may damage structural ligaments and allow excess vertebral movement that could expose the spinal cord to injury.

The Central Nervous System

The Brain

As discussed, the CNS is composed of the brain and spinal cord. The brain, which occupies 80% of the cranial vault, contains billions of neurons (nerve cells) that perform a variety of vital functions. The brain is the organ that controls the body, the center of consciousness. The major regions of the brain are the cerebrum, diencephalon (thalamus and

hypothalamus), brainstem (medulla, pons, mid-brain), and cerebellum. The remaining intracranial contents include cerebral blood and CSF, each occupying 10% (**FIGURE 30-6**).

The brain accounts for only 2% of total body weight, yet it is the most metabolically active and perfusion-sensitive organ in the body. The brain metabolizes 25% of the body's glucose, burning approximately 60 mg/min, and consumes 20% of the total body oxygen (about 45 to 50 mL/min). Because the brain has no storage mechanism for oxygen or glucose, it is totally dependent on cerebral blood flow (provided by carotid and vertebral arteries) for a constant flow of both fuels. The brain will continually manipulate the physiology as needed to guarantee that a ready supply of oxygen and glucose are available. A loss of blood flow to the brain for 5 to 10 seconds will result in unresponsiveness.

The Cerebrum

The **cerebrum** contains approximately 75% of the brain's total volume. It is responsible for higher functions, such as reasoning. The cerebrum is divided into right and left hemispheres.

The largest portion of the cerebrum is the **cerebral cortex**, which regulates voluntary skeletal movement and the level of awareness. Injury to the cerebral cortex may result in paresthesia, weakness, and paralysis of the extremities. Each cerebral hemisphere is divided into anatomic areas called lobes that control specific functions (**FIGURE 30-7**). The **frontal lobe** is responsible for voluntary motor action and personality traits. Injury to the frontal lobe may result in seizures or placid reactions

FIGURE 30-6 The major regions of the brain.

© Jones & Bartlett Learning.

FIGURE 30-7 Lobes of the cerebrum.

© Jones & Bartlett Learning.

(flat affect). (Recall that the frontal lobe filters the raw emotional impulses from the limbic system [FIGURE 30-8].) The **parietal lobe** impacts motor functions for the opposite (contralateral) side of the body by providing proprioception, and controls memory and emotions. Posteriorly, the

occipital lobe, from which the optic nerve originates, is responsible for processing visual information. After a blow to the back of the head, a person may “see stars,” which results when the occipital poles (vision centers) of the brain strike the back of the skull.

FIGURE 30-8 The limbic system is the seat of emotions, instincts, and other functions.

© Jones & Bartlett Learning.

The speech center is located in the **temporal lobe**. The temporal lobe also controls long-term memory, hearing, taste, and smell.

The Cerebellum

Inferior and posterior to the cerebrum lies the **cerebellum**, which coordinates body movements. *Cerebellum* is Latin for “little brain,” and it is sometimes called the “athlete’s brain” because it is responsible for the maintenance of posture and equilibrium and the coordination of skilled movements.

The Brainstem

The most primitive part of the CNS, the **brainstem**, controls virtually all functions that are necessary for life, including the cardiac and respiratory systems. Deep within the cranium, the brainstem is the best-protected part of the CNS.

The brainstem consists of the midbrain, pons, and the medulla. It is located at the base of the brain and connects the spinal cord to the remainder of the brain. The brainstem houses many structures that are critical to the maintenance of vital functions. High in the brainstem, for example, is the **reticular activating system (RAS)**, which is responsible for maintenance of consciousness, specifically

one’s level of arousal. The centers that control basic but critical functions—heart rate, blood pressure, and respiration—are located in the lower part of the brainstem. Damage to this area can easily result in cardiovascular derangement, respiratory arrest, or death.

The midbrain lies immediately below the diencephalon and is the smallest region of the brainstem. Deep within the cerebrum, diencephalon, and midbrain are the **basal ganglia**, which have an important role in coordination of motor movements and posture. The midbrain also controls pupillary size and reactivity.

The **pons**, which lies below the midbrain and above the medulla, contains numerous important nerve fibers, including those for sleep, respiration, and the medullary respiratory center—the portion of the respiratory center that is in the medulla oblongata.

The inferior portion of the midbrain, the **medulla**, is continuous inferiorly with the spinal cord and serves as a conduction pathway for ascending and descending nerve tracts. It also coordinates heart rate, blood vessel diameter, breathing, swallowing, vomiting, coughing, and sneezing. The vagus nerve (tenth cranial nerve), a bundle of nerves that primarily innervates the parasympathetic nervous system, originates from the medulla.

The Spinal Cord

The spinal cord transmits nerve impulses or signals between the brain and the rest of the body. It is composed of nerve fibers that extend from the brain’s nerve cells. Starting at the base of the brain, it represents the continuation of the CNS. This bundle of nerve fibers leaves the skull through a large opening at its base called the foramen magnum. The spinal cord extends from the base of the skull to approximately L2; here it terminates and forms into the **cauda equina**, a collection of individual nerve roots. In total, 31 pairs of spinal nerves arise from the different segments of the spinal cord; each pair is named according to its corresponding segment.

The Meninges

The **meninges** are protective layers that surround and enfold the entire CNS—specifically, the brain

FIGURE 30-9 The meninges.

© Jones & Bartlett Learning.

and spinal cord (**FIGURE 30-9**). The outermost layer is a strong, fibrous wrapping called the **dura mater** (meaning “tough mother”). The dura mater covers the entire brain, folding in to form the **tentorium**, a structure that separates the cerebral hemispheres from the cerebellum and brainstem. The meningeal arteries are located between the dura mater and the skull. Bleeding in this area results in an epidural hematoma because it is *above* the dura.

The dura mater is firmly attached to the internal wall of the skull. Just beneath the suture lines of the skull the dura mater splits into two surfaces and forms venous sinuses. When those venous sinuses are disrupted during a head injury, blood can collect beneath the dura mater to form a subdural hematoma.

The second meningeal layer is a delicate, transparent membrane called the **arachnoid**. It is so named because the blood vessels it contains resemble a spider web. The third meningeal layer, the **pia mater** (“soft mother”), is a thin, translucent, highly vascular membrane that firmly adheres directly to the surface of the brain.

The meninges float in CSF, which is manufactured in the ventricles of the brain. CSF flows in the

FIGURE 30-10 The peripheral nervous system is a complex network of motor and sensory nerves. The brachial plexus transmits messages to the arms, and the lumbosacral plexus transmits messages to the legs.

© Jones & Bartlett Learning.

subarachnoid space, located between the pia mater and the arachnoid.

The Peripheral Nervous System

Long fibers link the nerve cells to the body's various organs through openings in the bony coverings. These cables of nerve fibers make up the PNS. The PNS has two anatomic parts: 31 pairs of spinal nerves mentioned earlier, and 12 pairs of cranial nerves (**FIGURE 30-10**).

The Somatic Nervous System

The part of the nervous system that regulates or controls our voluntary activities, including almost all coordinated muscular activities, is called the **somatic nervous system**. The mechanism of the somatic nervous system is simple. The brain interprets the sensory information that it receives from the peripheral nerves and responds by sending signals to the voluntary muscles.

The body functions that occur without conscious effort are regulated by the much more primitive autonomic (involuntary) nervous system. The autonomic nervous system controls the functions of many of the body's vital organs, over which the brain has no voluntary control.

Words of Wisdom

A tip for remembering the names of the meningeal layers is to think of them as a “PAD” from the inside out. The innermost layer of the pad is the pia (P), the middle layer is the arachnoid (A), and the outer layer is the dura (D).

Words of Wisdom

CNS structures, whose bony enclosures protect them quite well, are also extremely fragile. Protecting them from further damage is vital to the patient's future ability to live a normal life. Lean toward caution and overprotection in assessing and treating possible brain and SCIs.

Cranial Nerves

Cranial nerves are the 12 pairs of nerves that pass through openings in the skull and transmit nerve impulses directly to or from the brain. They primarily perform special functions in the head and face, including sight, smell, taste, hearing, and facial expressions.

Peripheral Nerves

The 31 pairs of spinal nerves conduct sensory impulses from the skin and other organs to the spinal cord. They also conduct motor impulses from the spinal cord to the muscles. Because the arms and legs have so many muscles, the spinal nerves serving the extremities are arranged in complex networks. The brachial plexus controls the arms, and the lumbosacral plexus controls the legs.

There are two major types of peripheral nerves, sensory nerves and motor nerves. The **sensory nerves**, with endings that can perceive only one type of information each (such as temperature or texture), carry information from the body to the brain via the spinal cord. The **motor nerves**, one for each muscle, carry information from the CNS to the muscles. The **connecting nerves**, found only in the brain and spinal cord, connect the sensory and motor nerves with short fibers, which allow the cells on either end to exchange messages.

By connecting the sensory and motor nerves of the limbs, the connecting nerves in the spinal cord form a reflex arc. If a sensory nerve in this arc detects an irritating stimulus, such as heat, it will bypass the brain and send a message directly to the motor nerve, causing a response such as pulling away from the heat (**FIGURE 30-11**).

The Autonomic Nervous System

The Sympathetic Nervous System

The sensory (afferent) and motor (efferent) nerves are responsible for the somatic functions of the spinal cord and often overshadow the role of the spinal cord in the involuntary **autonomic nervous system**. The **sympathetic nervous system** is controlled by the brain's hypothalamus. Information from the brain is transmitted through the brainstem and the cervical

FIGURE 30-11 The connecting nerves in the spinal cord form a reflex arc. If a sensory nerve in this arc detects an irritating stimulus, it will bypass the brain and send a direct message to the motor nerve.

spinal cord and then exits at the thoracic and lumbar levels of the spine to reach target structures.

Certain fibers of the sympathetic nervous system stimulate the periphery largely through alpha and beta functions. Alpha receptor stimulation induces smooth muscle contraction in blood vessels and bronchioles. Beta receptor stimulation produces relaxation of smooth muscles in blood vessels and bronchioles and has chronotropic (affecting heart rate) and inotropic (affecting contractility) effects on myocardial cells. The sympathetic nervous system is also responsible for sweating, pupil dilation, and temperature regulation, as well as the shunting of blood from the periphery to the core during the fight-or-flight response.

SCI at or above the level of T6 may disrupt the flow of sympathetic communication. Loss of sympathetic stimulation can disrupt homeostasis and leave the body poorly equipped to deal with changes in its environment.

The Parasympathetic Nervous System

The **parasympathetic nervous system** is responsible for conserving energy and maintaining organ function. It includes fibers arising from the brainstem and upper spinal cord that carry signals to organs of the abdomen, heart, lungs, and the skin above the waist. The vagus nerve travels alongside the carotid arteries from its origin outside of the medulla to the heart; thus, vagal tone remains intact following a spine injury. Parasympathetic nerves that supply the reproductive organs, pelvis, and leg begin at the sacral level (S2 through S4). Disruption of the lower parasympathetic nerves in the sacrum results in the loss of bowel/bladder tone and sexual function.

Pathophysiology

Head Injuries

A head injury is a traumatic insult to the head that may result in injury to soft tissue, bony structures, and/or the brain. TBI is impairment of brain function brought about by an external force, such as a fall. According to the Brain Trauma Foundation (BTF), on average, 150 Americans die each day from TBI-related injuries.³ Approximately 30% of all traumatic deaths result from a TBI.² When head injuries are fatal, the cause is invariably associated injury to the brain. In addition to the head injury,

Special Populations

In older adults, SCI can result from seemingly minor falls. Decreased bone density or osteoporosis, arthritis, and general weakening of the ligaments and musculature of the neck in older adults contribute to increased risk of SCI. For example, a fall down a small flight of stairs may be enough to cause substantial injury to the spine.

Similarly, infants and children are more susceptible to direct brain injury because their skull formation along suture lines is not complete. This flexibility of the skull may also mask injuries that may be obvious in adolescents or adult patients. A force that compresses an adult skull and readily fractures it will not necessarily fracture a pediatric skull because the sutures may allow that same force to compress the pediatric brain without causing fracture.

and depending on the mechanism of injury (MOI), you should be alert to the fact that the patient may have sustained additional trauma such as cervical spine injuries, pelvic injuries, and chest injuries.

One way to categorize head injuries is open versus closed. A **closed head injury** (overwhelmingly the most common type) is usually associated with blunt trauma. Although the dura mater remains intact and brain tissue is not exposed to the environment, closed head injuries may result in skull fractures, focal brain injuries, or diffuse brain injuries. Furthermore, these injuries are often complicated by increased **intracranial pressure (ICP)**.

With an **open head injury**, the dura mater and cranial contents are penetrated, and brain tissue is open to the environment. Gunshot wounds—the most common penetrating MOI—have a high mortality rate, and for those who survive there is almost always substantial neurologic deficit and a decreased quality of life.

Open and closed head injuries have essentially the same signs and symptoms. Following an injury, any patient who exhibits one or more of the signs or symptoms listed in **TABLE 30-1** should be evaluated promptly in the ED.

Scalp Lacerations

Scalp lacerations can be minor or serious. Because both the face and the scalp have rich blood supplies, even small lacerations can quickly result in

TABLE 30-1 Signs and Symptoms of Head Trauma**Head Injury**

Lacerations, contusions, or hematomas to the scalp

Soft area or depression noted on palpation of the scalp

Visible skull fractures or deformities

Battle sign or raccoon eyes

CSF rhinorrhea or otorrhea

Traumatic Brain Injury

Pupillary abnormalities

- Unequal pupil size
- Sluggish or nonreactive pupils

A period of unresponsiveness

Confusion or disorientation

Repeatedly asks the same questions (perseveration)

Amnesia (retrograde and/or anterograde)

Combativeness or other abnormal behavior

Numbness or tingling in the extremities

Loss of sensation and/or motor function

Focal neurologic deficits

Seizures

Cushing triad: hypertension, bradycardia, and irregular or erratic respirations

Dizziness

Visual disturbances, blurred vision, or double vision (diplopia)

Seeing “stars” (flashes of light)

Nausea or vomiting

Posturing (decorticate and/or decerebrate)

substantial blood loss (**FIGURE 30-12**). This blood loss may be severe enough at times to cause hypovolemic shock, particularly in children. In any patient with multiple injuries, bleeding from scalp or facial lacerations may contribute to hypovolemia.⁴ In addition, because scalp lacerations are usually

**FIGURE 30-12** Substantial blood loss can stem from a small laceration on the face or scalp.

© Martin Hunter/Stringer/Getty Images Sport/Getty Images.

the result of direct blows to the head, they often indicate deeper, more serious injuries.

Skull Fracture

Substantial force applied to the head may cause a skull fracture. As with any fracture, a skull fracture may be open or closed, depending on whether there is an overlying laceration of the scalp. Injuries from bullets or other penetrating weapons frequently result in open fractures. The diagnosis of a skull fracture is usually made in the hospital with a computed tomography (CT) scan, but you should maintain a high index of suspicion that a fracture is present if the patient's head appears deformed or if there is a visible crack in the skull within a scalp laceration. Additional signs of skull fracture that you may see include ecchymosis (bruising) that develops under the eyes (**raccoon eyes**) (**FIGURE 30-13A**)

A

B

FIGURE 30-13 Suspect a basilar skull fracture if a head trauma patient has ecchymosis. **A.** Ecchymosis under or around the eyes (raccoon eyes). **B.** Ecchymosis behind the ear over the mastoid process (Battle sign).

or behind one ear over the mastoid process (**Battle sign**) (**FIGURE 30-13B**). Skull fractures can be categorized into four types (**FIGURE 30-14**).

Linear Skull Fractures

Linear skull fractures (nondisplaced skull fractures) account for most skull fractures.⁵ Radiographs are required to diagnose a linear skull fracture because often there are no physical signs (such as deformity). If the brain is uninjured and there are no scalp lacerations, linear fractures are not life threatening. However, if a scalp laceration occurs in conjunction

A

B

C

D

FIGURE 30-14 Types of skull fracture. **A.** Linear. **B.** Depressed. **C.** Basilar. **D.** Open.

© Jones & Bartlett Learning.

with a linear fracture—making it an open fracture—there is a risk of infection.

Depressed Skull Fractures

Depressed skull fracture results from high-energy direct trauma to the head with a blunt object (such as a baseball bat to the head). The frontal and parietal regions of the skull are most susceptible to this type of fracture because the bones in these areas are relatively thin. Consequently, bony fragments may be driven into the brain, resulting in injury. The scalp may or may not be lacerated. Patients with depressed skull fractures often present with neurologic signs (such as unresponsiveness).

Basilar Skull Fractures

Basilar skull fracture also is associated with high-energy trauma, but usually occurs following diffuse impact to the head (eg, falls, motor vehicle crashes). This injury generally results from extension of a

FIGURE 30-15 Blood draining from the ear after a head injury may contain cerebrospinal fluid and suggests a basilar skull fracture.

© Jones & Bartlett Learning.

linear fracture to the base of the skull and can be difficult to diagnose without a CT scan.

Signs of a basilar skull fracture include CSF drainage from the ears (**FIGURE 30-15**), which indicates rupture of the tympanic membrane and freely flowing CSF through the ear. Patients with leaking CSF are at risk for bacterial meningitis.

Other signs of a basilar skull fracture include raccoon eyes or Battle sign. Depending on the extent of the damage, raccoon eyes and Battle sign may appear relatively quickly, but in many cases, they may not appear until up to 24 hours following the injury, so their absence in the field does not rule out a basilar skull fracture.

Open Skull Fractures

Open fractures of the cranial vault result when severe forces are applied to the head and are often associated with trauma to multiple body systems. Brain tissue may be exposed to the environment, which substantially increases the risk of a bacterial infection (such as bacterial meningitis). Open cranial vault fractures have a very high mortality rate.

Traumatic Brain Injuries

TBIs can be classified into two broad categories: primary (direct) injury and secondary (indirect) injury. **Primary brain injury** is injury to the brain and its associated structures that results instantaneously from impact to the head and resultant transmission of force to brain tissue. **Secondary brain injury** is a consequence of primary injury and results

from the sequelae of the primary brain injury, including **cerebral edema**, intracranial hemorrhage, increased ICP, cerebral ischemia and hypoxia, and infection. Two other significant causes of secondary brain injury that are potentially preventable in the prehospital setting are hypoxia and hypotension. According to the BTF, hypoxia and hypotension (systolic blood pressure less than 90 mm Hg) are both predictors of poor outcome in the patient with a TBI.⁶ If the patient has a single incident of hypotension, regardless of the amount of time, then mortality increases from two to four times that of patients who did not experience hypotension. Hypoxia has similar effects, and the combination of hypotension and hypoxia has exponential effects on mortality. Secondary brain injury can occur anywhere from a few minutes to several days following the initial injury.

The brain can be injured directly by a penetrating object, such as a bullet, knife, or other sharp object. More commonly, such injuries occur indirectly, as a result of external forces exerted on the skull.

Consider the most common cause of brain injury, the motor vehicle crash. When the passenger's head hits the windshield on impact with a fixed object, the brain continues to move forward until it comes to an abrupt stop by striking the inside of the skull. This rapid deceleration results in compression injury (or bruising) to the anterior portion of the brain along with stretching or tearing of the posterior portion of the brain (**FIGURE 30-16**).

As the brain strikes the front of the skull, the body begins its path of moving backward. The head falls back against the headrest and/or seat, and the brain slams into the rear of the skull. This type of front-and-rear injury is known as a **coup-contrecoup injury**. The same type of injury may occur on opposite sides of the brain in a lateral collision.

The injured brain starts to swell, initially because of cerebral vasodilation. An increase in cerebral edema then contributes to further brain swelling. Cerebral edema may not develop until several hours following the initial injury, however.

Low oxygen levels in the blood aggravate cerebral edema. For this reason, you must make sure that the airway is open and that adequate ventilation and high-flow oxygen are given to all patients with a TBI. This is especially true if the patient is unresponsive. Do not wait for cyanosis or other obvious signs of hypoxia to develop.

FIGURE 30-16 For the unrestrained person in a motor vehicle crash, the brain continues its forward motion and strikes the inside of the skull, resulting in compression injury to the anterior portion of the brain and stretching of the posterior portion.

© Jones & Bartlett Learning.

However, it is important to remember that the patient should *not* be hyperventilated. The only indication for hyperventilation is evidence of cerebral **herniation** such as a unilateral dilated pupil that is unresponsive to light or a decrease by 2 or more points in the **Glasgow Coma Scale (GCS)** in a patient whose GCS score is less than 8. Even then, hyperventilation should be minimal and performed only in the context of a complete ability to monitor end-tidal carbon dioxide (ETCO₂) carefully. Remember that hyperventilation has the effect of decreasing cerebral blood flow! In general, patients should be ventilated at a normal, age-appropriate rate.

Special Populations

A modified GCS for pediatric and nonverbal patients assesses eye opening, verbal response, and motor response. The scoring indicators are the same as the GCS but the modified scale takes into consideration responses of coos and babbling, scoring these responses as oriented and appropriate.

A common response to head injuries, especially among children with slight head injuries, is vomiting. This is usually the result of increased ICP.

As discussed earlier, the appearance of clear or pink, watery CSF from the nose, the ear, or an open scalp wound indicates that the dura and the skull have both been disrupted.

Words of Wisdom

When the brain is deprived of oxygen and carbon dioxide levels are elevated, the vessels dilate to bring more oxygenated blood to the hypoxic tissue. Increasing vessel size in an already cramped environment then increases ICP, making it even harder for blood to flow to the swollen tissues. On the opposite side of the spectrum, hyperventilating will decrease vessel size, thereby diminishing blood flow and, again, diminishing oxygenation to deprived brain cells. It is important to ventilate the patient at a normal rate with high-flow oxygen while monitoring for changes in vital signs, pupils, and mental status.

It is not uncommon for a patient with a head injury to have a seizure. This is the result of excessive excitability of the brain, caused by direct injury or the accumulation of fluid within the brain (edema). Be prepared to manage seizures in all patients who have had a TBI.

Words of Wisdom

The effects of cerebral edema and increased ICP produce the signs that are collectively known as the **Cushing triad**:

- Increased blood pressure
- Decreased pulse
- Irregular respirations

Intracranial Pressure

Bleeding inside the skull increases ICP, the pressure within the cranial vault. Bleeding can occur between the skull and dura mater, beneath the dura mater but outside the brain, within the tissue of the brain itself, or into the subarachnoid space. Increased ICP squeezes the brain against the cranium.

Healthy adult ICP ranges from 5 to 15 mm Hg. An increase in ICP (such as from cerebral edema or intracranial hemorrhage) decreases cerebral

perfusion pressure and cerebral blood flow. **Cerebral perfusion pressure (CPP)**, the pressure of blood flow through the brain, is the difference between the **mean arterial pressure (MAP)**, the average (or mean) pressure against the arterial wall during a cardiac cycle, and ICP ($CPP = MAP - ICP$). Decreasing cerebral blood flow is a potential catastrophe because the brain depends on a constant supply of blood to supply the oxygen and glucose it needs to survive.

The critical minimum threshold, or minimum CPP required to adequately perfuse the brain, is 60 mm Hg in the adult. A CPP of less than 60 mm Hg will result in cerebral ischemia, potentially resulting in permanent neurologic impairment or even death.

The body responds to a decrease in CPP by increasing MAP, resulting in cerebral vasodilation and increased cerebral blood flow; this process is called **autoregulation**. However, an increase in cerebral blood flow causes a further increase in ICP. As ICP continues to increase, CSF is forced from the cranium into the spinal cord.

The patient with increased ICP is caught in a vicious cycle. As ICP increases, cerebral blood flow increases secondary to autoregulation, which results in a potentially fatal increase in ICP. Conversely, if cerebral blood flow decreases, CPP decreases as well, and the brain becomes ischemic.

ICP and CPP cannot be measured in the field, but the severity of increased ICP can be estimated based on the patient's clinical presentation. Pre-hospital treatment must focus on maintaining CPP (and cerebral blood flow), while preventing increased ICP as much as possible. If increased ICP is not promptly treated in a definitive care setting, cerebral herniation may occur (the brain is forced from the cranial vault).

You must closely monitor the patient with head injury for signs and symptoms of increased ICP. The exact clinical signs encountered depend on the amount of pressure inside the skull and the extent of brainstem involvement (**TABLE 30-2**). Early signs and symptoms include vomiting (often without

TABLE 30-2 Levels of Intracranial Pressure

Elevation Level	Clinical Indicators
Mild elevation	- Increased blood pressure; decreased pulse rate - Pupils still reactive Cheyne-Stokes respirations (respirations that are fast and then become slow, with intervening periods of apnea) - Patient initially attempts to localize and remove painful stimuli; this is followed by withdrawal and extension - Vomiting (often without nausea) - Headache - Altered level of consciousness - Seizures - Effects usually reversible <i>with prompt and appropriate treatment</i>
Moderate elevation (indicates middle brainstem involvement)	- Widened pulse pressure and bradycardia - Pupils are sluggish or nonreactive Central neurogenic hyperventilation (deep, rapid respirations; similar to Kussmaul, but without an acetone odor on breath) - Decerebrate posturing - Survival possible but often with some permanent neurologic deficit
Marked elevation (indicates involvement of lower portion of brainstem/medulla)	- Unilaterally fixed and dilated (blown) pupil Biot respirations (irregular pattern, rate, and depth of breathing with intermittent periods of apnea) or absent respirations; also called ataxic respirations - Flaccid response to painful stimuli - Irregular pulse rate - Fluctuating blood pressure; hypotension is common - Most patients do not survive this level of intracranial pressure

Data from: Stiver SI, Gean AD, Manley GT. Survival with good outcome after cerebral herniation and Duret hemorrhage caused by traumatic brain injury. *J Neurosurg*. 2009;110(6):1242-1246.

nausea), headache, an altered level of consciousness, and seizures.

Later, more ominous signs include hypertension (with a widening pulse pressure), bradycardia, and irregular respirations (Cushing triad), plus a unilaterally unequal and nonreactive pupil (caused by oculomotor nerve compression), coma, and posturing. **Decorticate (flexor) posturing** is characterized by flexion of the arms and extension of the legs; **decerebrate (extensor) posturing** is characterized by extension of the arms and legs (**FIGURE 30-17**). When observed, posturing is an ominous sign and indicates substantial increase in ICP.

Focal Brain Injuries

Brain injuries can also be broadly classified as focal or diffuse. A **focal brain injury** is a specific, grossly observable brain injury (ie, it can be seen on a CT scan). Such injuries include cerebral contusions and intracranial hemorrhage.

Cerebral Contusion

In a **cerebral contusion**, brain tissue is bruised and damaged in a specific area. A cerebral contusion is different than a **concussion** because it involves physical damage to the brain, potentially

causing greater neurologic deficits (eg, prolonged confusion, loss of consciousness). The same MOIs that cause concussions—acceleration-deceleration forces and direct blunt head trauma—also cause cerebral contusions.

A

B

FIGURE 30-17 Posturing indicates substantial intracranial pressure. **A.** Decorticate (flexor) posturing. You can remember this term by thinking of the arms being pulled to the core of the body. **B.** Decerebrate (extensor) posturing.

YOU are the Provider

Part 2

Ensuring that spinal precautions are being maintained, you quickly palpate the patient's skull and find a large hematoma on his posterior scalp. Continuing your examination, you find that the patient has no sensation or active movement in his arms or legs; the patient does have a readily palpable pulse at bilateral wrists. You direct your partner to place a cervical collar on the patient, as you place the patient on a nonbreathing mask at 15 L/min. After the cervical collar is secured, you strap the patient onto the long backboard and load him onto the stretcher. As you begin your vital sign assessment, you calculate his GCS and determine it to be 10. He is alert (4) and oriented (5), but has no motor function (1).

Recording Time: 1 Minute

Appearance	Fair
Level of consciousness	Alert and oriented
Airway	Patent
Breathing	Irregular
Circulation	Warm and dry

- What would you expect this patient's vital signs to be?
- What are the signs and symptoms of a basilar skull fracture?

FIGURE 30-18 An epidural hematoma is usually the result of a blow to the head that produces a linear fracture of the temporal bone and damages the middle meningeal artery. Blood accumulates between the dura mater and the skull.

© Jones & Bartlett Learning.

The area of the brain most commonly affected by a cerebral contusion is the frontal lobe, although multiple areas of contusion can occur, especially following coup-contrecoup injuries. As with any bruise, swelling will occur. This swelling may result in increased ICP. A patient who has sustained a brain contusion may exhibit any or all signs of brain injury.

Epidural Hematoma

An **epidural hematoma** is an accumulation of blood between the skull and dura mater (**FIGURE 30-18**). An epidural hematoma is nearly always the result of a blow to the head that produces a linear fracture of the thin temporal bone. The middle meningeal artery courses along a groove in that bone, so it is susceptible to disruption when the temporal bone is fractured.⁷ In such a case, brisk arterial bleeding into the epidural space will result in rapidly progressing symptoms.

In the classic presentation, the patient becomes unresponsive immediately following the injury, which is then followed by a brief period of awareness (lucid interval), after which the patient lapses back into unresponsiveness.⁸ Meanwhile, as ICP increases, the pupil on the side of the hematoma becomes fixed and dilated. Death will follow rapidly without surgery to evacuate the hematoma.

Subdural Hematoma

A **subdural hematoma** is an accumulation of blood beneath the dura mater but outside the brain

FIGURE 30-19 In a subdural hematoma, venous bleeding occurs beneath the dura mater but outside the brain.

© Jones & Bartlett Learning.

(**FIGURE 30-19**). Although the exact incidence varies among studies, subdural hemorrhages are the most common type of intracranial hemorrhage and may or may not be associated with a skull fracture. Bleeding within the subdural space typically results from rupture of the veins that bridge the cerebral cortex and dura.

A subdural hematoma is associated with venous bleeding, so this type of hematoma—and the signs of increased ICP—typically develops more gradually than with an epidural hematoma. The patient with a subdural hematoma often experiences a fluctuating level of consciousness, focal neurologic signs (such as unilateral hemiparesis), or slurred speech.

Subdural hematomas are classified as acute (clinical signs developing within 48 hours following injury), subacute (signs developing between 2 and 14 days after the injury), or chronic (symptoms may not appear for as long as 2 weeks). Chronic subdural hematomas are more common in older adults, patients with alcoholism, patients with bleeding disorders (such as hemophilia), and patients taking anticoagulants (such as warfarin).^{9,10}

Special Populations

Older adults and those with a history of alcohol use are at higher risk for development of a subdural hematoma. This is caused by atrophy of the brain tissue that increases stretching of the bridging veins. Signs and symptoms of the condition may not occur for several hours, days, or weeks. Be sure to obtain a thorough history of any previous trauma.

FIGURE 30-20 An intracerebral hematoma involves bleeding within the brain tissue itself.

© Jones & Bartlett Learning.

Intracerebral Hematoma

An **intracerebral hematoma** involves bleeding within the brain tissue itself (**FIGURE 30-20**). This type of injury can occur following a penetrating injury to the head or because of rapid deceleration forces.

Many small, deep intracerebral hemorrhages are associated with other brain injuries, such as diffuse axonal injury, discussed later in this chapter. After symptoms appear, the patient's condition often deteriorates quickly. Intracerebral hematomas have a high mortality rate, even if the hematoma is surgically evacuated.

Subarachnoid Hemorrhage

In a **subarachnoid hemorrhage**, bleeding occurs into the subarachnoid space, where the CSF circulates. It results in bloody CSF and signs of meningeal irritation (such as nuchal rigidity and headache). Common causes of a subarachnoid hemorrhage include trauma or rupture of an aneurysm or arteriovenous malformation.

Many, but not all, patients with a subarachnoid hemorrhage present with a sudden, severe headache.¹¹ As bleeding into the subarachnoid space increases, the patient experiences the signs and symptoms of increased ICP: decreased level of consciousness, pupillary changes, posturing, vomiting, and seizures. A sudden, severe subarachnoid hemorrhage usually results in death.¹² People who survive often have permanent neurologic impairment.

Diffuse Brain Injuries

A **diffuse brain injury** is any injury that affects the entire brain. These injuries include cerebral concussion and diffuse axonal injury.

Cerebral Concussion

A blow to the head or face may cause a cerebral concussion of the brain if the brain is jarred around in the skull. This kind of mild brain injury is usually caused by rapid acceleration-deceleration forces (coup-contrecoup), such as those seen following motor vehicle crashes or falls.

Concussions are mild TBIs. A concussion injury results in cerebral dysfunction that *usually* resolves spontaneously and rapidly without demonstrable physical damage to the brain or permanent neurologic impairment. Loss of consciousness may occur, but in most cases, the patient remains alert.

The exact definition of concussion continues to evolve as we learn more about this injury. The 5th International Conference on Concussion in Sport in 2016 defined concussion as a TBI induced by biomechanical forces. Common features that may be used in clinically defining a concussion include the following four items when the signs and symptoms cannot be explained by drug, alcohol, or medication use, or other injuries or comorbidities:¹³

- Concussion may be caused by either a direct blow to the head or a blow to the face, neck, or elsewhere on the body with an impulsive force transmitted to the head.
- Concussion typically results in the rapid onset of short-lived impairment of neurologic function that resolves spontaneously. However, in some cases, signs and symptoms may evolve over several minutes to hours.
- Concussion may result in neuropathologic changes, but the acute clinical symptoms largely reflect a functional disturbance rather than a structural injury; therefore, no abnormality is seen on standard structural neuroimaging studies.
- Concussion results in a range of clinical signs and symptoms that may or may not involve a loss of consciousness. Resolution of the clinical and cognitive features typically follows a sequential course. However, in some cases symptoms may be prolonged.

In the United States, more than 300,000 sports-related concussions occur annually, and many of these patients do not seek immediate medical treatment.¹⁴ As a result, you may very well encounter patients with a concussion days after the event.

A great deal has been learned about concussions over the past several years. Researchers have exposed the damaging effects of repetitive concussions and the risk of second impact syndrome and postconcussion syndrome. You must not discount patients with possible concussions regardless of whether you see them at the time of the injury or days to weeks after the concussive event. Do not let helmet use decrease your suspicion of a concussion. Although studies have shown that helmets reduce head and facial injury and absorb energy that would otherwise act on the brain, they have not been shown to eliminate the incidence of concussions.

Athletic venues are a common site of concussions. You may be on standby for the event or be called to the event after the injury. Some youth coaches are required to take concussion training. Upper levels of play usually include athletic trainers who have undergone extensive concussion training and may have conducted a prescreening of the injured athlete that they can use for comparison.

At times, you may be the only medical professional on scene. One of the biggest questions in these situations is whether the athlete can return to play. Currently there is no diagnostic test that can reliably be used for an immediate determination of the presence of a concussion. Therefore, it is impossible to rule out a concussion in the setting of a head injury with transient neurologic symptoms. Any time a concussion is suspected, the player must be removed from play and assessed by a physician.¹³ Authorizing an athlete to return to play after a potential concussion is outside the AEMT's scope of practice. If you are faced with this decision, then consult medical direction.

If you face a situation in which a coach or parent wants to return the athlete to the game, but you think the player should not return, then explain your concerns to the coach and/or athletic trainer. Point out the signs and symptoms you observe and remind all involved of the steps in the concussion action plans developed by the National Federation of State High School Associations in association with the Centers for Disease Control and Prevention's "Heads Up" program (**FIGURE 30-21**).^{15,16} Both organizations offer free concussion training on their websites.

Signs of a concussion include confusion and disorientation that may last for several minutes.

Retrograde amnesia, a loss of memory relating to events that occurred before the injury, or **anterograde (posttraumatic) amnesia**, a loss of memory relating to events that occurred after the injury, may follow a concussion.

Usually, a concussion lasts only a short time. In fact, it has often resolved by the time you arrive. Nevertheless, you should ask about symptoms of concussion in any patient who has sustained an injury to the head; these symptoms include dizziness, weakness, or visual changes. Additional signs and symptoms you may encounter with a patient who has sustained a concussion may include nausea or vomiting, and the patient may report ringing in the ears. Slurred speech and the inability to focus may also be present. Depending on the severity of the concussion, you may also notice that the patient has a lack of coordination, has a delay of motor functions, or displays inappropriate emotional responses. Patients may also report a temporary headache and may appear to be disoriented at times.

Patients with symptoms consistent with concussion can also have more serious underlying brain injury. A CT scan is necessary to differentiate between these conditions. You should always assume that a patient with ongoing signs or symptoms of concussion has a more serious injury until proven otherwise by a CT scan at the hospital or by evaluation by a physician.

Diffuse Axonal Injury

Diffuse axonal injury (DAI), like a concussion, is a global injury to the brain without a discrete focus of damage demonstrable on an imaging study such as CT or magnetic resonance imaging (MRI). Unlike a concussion, however, this far more severe brain injury is often associated with an extremely poor prognosis. DAI involves stretching, shearing, or tearing of nerve fibers with consequent axonal damage.¹⁷ An **axon** is a long, slender extension of a neuron (nerve cell) that conducts electrical impulses away from the **neuronal soma** (cell body) in the brain.

DAI most often results from high-speed, rapid acceleration-deceleration forces, such as motor vehicle crashes and falls from a significant height. The severity and, thus, the prognosis of DAI depend on the degree of damage (ie, stretching versus shearing or tearing); DAI is classified as being mild, moderate, or severe.

Spine Injuries

The cervical, thoracic, and lumbar portions of the spine can be injured in a variety of ways. Compression injuries can occur as a result of a fall, regardless of whether the patient's impact is at the feet, coccyx, or, as in diving accidents, the top of the head. Motor vehicle crashes or other types of trauma can overextend, flex, or rotate the spine. Any one of these unnatural motions, as well as excessive lateral bending, can result in fractures and neurologic deficits.

Mechanism of Injury

Acute injuries of the spine are classified according to the associated mechanism, location, and stability of the injury. Vertebral fractures can occur with or without associated SCI. Stable fractures pose less risk to the spinal cord. Unstable injuries involve multiple columns of the spine and are often

associated with damage to portions of the vertebrae and ligaments that directly protect the spinal cord and nerve roots. Without appropriate treatment, unstable injuries carry a higher risk of complicating SCI and progression of injury.

Flexion Injuries

Flexion injuries result from forward movement of the head, typically as the result of rapid deceleration (eg, in a car crash) or from a direct blow to the occiput. These forces can produce an unstable dislocation with or without an associated fracture.

Patients can also experience lateral bending, which is similar to a flexion injury. In flexion-compression mechanisms, the patient's head moves from front to back and is overstretched on one side while being overcompressed on the opposite side. With lateral bending, the patient experiences the same type of injury, but from left to right rather than from front to back.

Words of Wisdom

Subluxation is an incomplete or partial dislocation that can be associated with SCI but is more commonly associated with no neurologic injury or a single nerve root injury. It is typically caused by a flexion-rotation MOI, but is possible with other mechanisms. Findings typically include neck pain, with or without neurologic symptoms.

Rotation With Flexion

The only area of the spine that allows for substantial rotation is C1-C2. Injuries to this area are often unstable because of its high cervical location and relatively limited bony and soft-tissue support. Rotation in other areas of the spine is more limited, and rotation forces in these areas can result in injury. **Flexion-rotation injuries** (in which both rotation and flexion occur) result often from high-velocity mechanisms.

Vertical Compression

Vertical compression forces are transmitted through vertebral bodies and directed either inferiorly through the skull or superiorly through the pelvis or feet. They typically result from a direct blow to the crown (parietal region) of the skull or rapid deceleration from a fall through the feet, legs, and pelvis (more common). Forces transmitted through the vertebral body cause fractures, ultimately shattering and producing a “burst” or compression fracture with or without associated SCI (**FIGURE 30-22**). Compression forces can cause the herniation of disks, subsequent compression on the spinal cord and/or nerve roots, and fragmentation into the canal.

Although most fractures resulting from these injuries are stable, primary SCI can occur when the vertebral body is shattered and fragments of bone become embedded, resulting in compression of the cord. Although very rare, some compression injuries in the cervical spine can also cause serious airway compromise.

Hyperextension and Distraction

Hyperextension of the head and neck (extension beyond the usual range of motion) can result in fractures of bones and injury to ligaments.

FIGURE 30-22 A compression fracture of the spine.

© Jones & Bartlett Learning.

FIGURE 30-23 Distraction spinal injury.

© Jones & Bartlett Learning.

Any time the spine undergoes **distraction**, or is pulled along its length, you can expect to find serious injuries to the spine. Distraction forces are the opposite of compression (axial) forces. Distraction occurs from rapid deceleration of the skull, atlas, and axis as a unit; it results when parts of the body are pulled in opposite directions (**FIGURE 30-23**). Consider someone who has been hanged. The

individual is moving and is jerked to a stop at one point while gravity pulls the rest of the body away from the fixed end. The result is stretching and separation of the spinal column, its ligaments, and its supporting muscles and potentially stretching or even tearing of the spinal cord. Although the type of distraction force determines the MOI, the cervical region is most vulnerable to distraction forces because it has the least support and protection.

Words of Wisdom

A *distracting injury* is not the same as a distraction injury. A distracting injury is an injury to another body part or system (such as a femur fracture) that causes such substantial pain and discomfort that it sufficiently distracts the patient's attention, rendering the patient an unreliable reporter—that is, the patient is unable to report whether there are any signs or symptoms of an occult spinal column injury.

A *distraction injury* is one in which a physical distraction mechanism causes separation of bony fragments or joint surfaces. This MOI can cause separation of spinal column elements and potential SCI. It is important to clearly recognize the difference between these two terms in evaluating patients with possible spinal column or cord injuries and when determining patients who may be safely managed without spinal motion restriction (SMR).

The most classic distraction injury is a **hangman's fracture**, which, as its name implies, occurs during a hanging. In addition to distraction forces caused as the rope pulls tight, the rope causes a severe lateral force, snapping the head sideways as the spine stretches. The result is a bilateral fracture of C2 with an associated traumatic subluxation of C2 on C3.

Distraction or compression mechanisms frequently do not occur alone. Mixed mechanisms with some sort of rotation, flexion, or extension forces usually occur together. Carefully examine the incident and identify the forces that may have been involved. This information will enable you to better understand the type of injuries the patient may have sustained.

Spinal Cord Injuries

Signs and symptoms of SCI are listed in **TABLE 30-3**. Note that the ability to feel or move does not rule out the possibility of a spinal injury existing.

TABLE 30-3 Signs and Symptoms of Spinal Cord Injury

Tenderness at the injury site
Pain
Obvious deformity on palpation of the spine
Soft-tissue injuries in the spinal region
Numbness, weakness, or tingling in the extremities
Inability to feel below a certain point on the body
Inability to feel the extremities
Difficulty breathing, shallow breathing
Hypotension
Loss of bladder/bowel control
Inability to maintain body temperature
Priapism (a persistent erection lasting more than 4 hours)

© Jones & Bartlett Learning

Patients with severe spinal injury may lose sensation or experience paralysis below the suspected level of injury or be incontinent (**FIGURE 30-24**). Obvious injury to the head and neck may indicate injury to the cervical spine. Injury to the shoulders, back, or abdomen may indicate injury to the thoracic or lumbar spine. Injuries of the lower extremities may indicate associated injuries of the lumbar spine or sacrum.

Injuries to the cervical area can limit the ability of the diaphragm to function fully and minimize the ability of the chest wall to fully expand. One sign of spinal injury is abdominal excursion—the patient is unable to expand the chest wall to breathe by contracting the intercostal muscles but still has diaphragmatic function to allow for inspiration and expiration.

Primary Spinal Cord Injury

Primary spinal cord injury occurs at the moment of impact. Penetrating trauma typically results in transection of neural elements that are incapable of regeneration. Blunt trauma may displace ligaments and bone fragments, resulting in compression of points of the spinal cord or an incomplete

FIGURE 30-24 With severe spinal injuries, patients may lose sensation or experience paralysis below the suspected level of injury.

© Jones & Bartlett Learning.

dislocation of the vertebral body. Hypoperfusion and ischemia may also result from this type of injury to the spinal vasculature. Necrosis from prolonged ischemia leads to permanent loss of function.

Spinal cord concussion is characterized by a temporary dysfunction that lasts from 24 to 48 hours. Cord concussion is considered an incomplete injury and may present in patients with simple compression fractures or in patients with no fracture at all. **Spinal cord contusion** is caused by fracture, dislocation, or direct trauma. It is associated with edema, tissue damage, and vascular leakage. Finally, cord laceration can occur when a projectile or bone enters the spinal canal. Such an injury is likely to result in hemorrhage into the cord tissue, swelling, and disruption of some portion of the cord and its associated communication pathways.

Secondary Spinal Cord Injury

Secondary spinal cord injury results from primary SCI progressing to further deterioration. These effects can be exacerbated by exposing neural elements to further hypoxemia, hypoglycemia, and hypothermia. Although some SCI may be unavoidable, you should minimize risk of further injury through stabilization, neutral alignment, and spinal column immobilization. In addition, minimizing heat loss and maintaining oxygenation and perfusion are key elements in the care of a patient with a possible SCI.

Spinal Shock

Spinal shock refers to the temporary local neurologic condition that occurs immediately after spinal trauma. Swelling and edema of the cord begin within 30 minutes of the initial insult and can lead to a physiologic transection, mechanically disrupting all nerve conduction distal to the injury. The patient may present with varied degrees of acute spinal injury, potentially with flaccid paralysis, flaccid sphincters, and absent reflexes. Sensory function below the level of injury will be impaired, as will thermoregulation and visceral sensation below the lesion, resulting in bowel distention from a loss of peristalsis. Spinal shock usually subsides in hours to weeks, depending on the severity of injury.¹⁸

Neurogenic Shock

Neurogenic shock results from the temporary loss of autonomic function, which controls cardiovascular function, at the level of injury. Hypotension occurs because of absent or impaired peripheral vascular tone with the loss of alpha receptor stimulation; blood pools in the enlarged vascular space, causing a relative hypovolemia and making the patient extremely sensitive to sudden position changes; and cardiac preload decreases, resulting in decreased stroke volume and cardiac output. Bradycardia results as well. The adrenal gland loses its sympathetic stimulation and does not produce epinephrine or norepinephrine. Hypothermia and absence of sweating are also seen because of the loss of sympathetic stimulation. The classic case of neurogenic shock is a hypotensive, bradycardic patient whose skin is warm, flushed, and dry below the level of the spinal lesion.

Patient Assessment

Scene Size-up

After you have taken standard precautions, the initial step of any assessment is to make a determination about scene safety and consider the need for any additional resources. Decide whether the trauma system should be activated (eg, air evacuation of the patient to a Level I trauma center). Also consider the need for paramedic backup.

Motor vehicle crashes, direct blows, falls from heights, assault, and sports-related injuries are common causes of head injuries and TBIs. When your patient has experienced any of these events, it should immediately increase your index of suspicion and prompt a search for signs and symptoms of these types of injuries. A damaged windshield or dented or cracked helmet indicates a major blow to the head (**FIGURE 30-25**).

Later in this chapter, specific indications for SMR (also called spinal immobilization) are discussed. The decision of whether to immobilize a patient depends on your local protocols, and this decision is not usually based purely on MOI. However, the following high-risk mechanisms of injury strongly suggest the possibility of

FIGURE 30-25 The classic “star” on the windshield after an automobile crash is an important indicator of injury. Be alert for the signs and symptoms of head and cervical spine injury.

© Kristin Smith/Shutterstock.

spine injury¹⁹ and indicate that SMR should be considered:

- High-velocity crash (greater than 40 mph) with severe vehicle damage
- Unrestrained occupant of moderate- to high-speed motor vehicle crash
- Vehicular damage with compartmental intrusion (12 inches [30 cm]) into the patient’s seating space
- Fall of an adult from a height greater than 20 feet (6 m)
- Fall of a child from a height of greater than 10 feet (3 m), or a height two to three times the child’s height
- Penetrating trauma near the spine
- Ejection from a moving vehicle
- Motorcycle crash of greater than 20 mph
- Auto-pedestrian or auto-bicycle crash of greater than 20 mph
- Death of occupant in the same passenger compartment
- Rollover crash (unrestrained)

Diving is also considered a high-risk MOI,²⁰ especially when it involves injury to the head or a witness who saw a deep dive in the shallow end of a swimming pool.

Mechanisms of uncertain risk for spinal injury include the following:

- Moderate- to low-velocity motor vehicle crash (less than 40 mph)
- Motor vehicle crash in which the patient has an isolated injury without positive assessment findings for spinal injury
- Isolated minor head injury without positive mechanism for spinal injury
- Syncopal event in which the patient was already seated or supine
- Syncopal event in which the patient was assisted to a supine position by a bystander

Words of Wisdom

The most important single sign in the evaluation of a patient with a head injury is an altered or changing mental status.

Safety

Many mechanisms that cause head and spine injuries for the patient can also entail risk to emergency responders. Before you approach the patient, get the “big picture” of scene safety and take any actions necessary to ensure your own well-being. Do not rely entirely on assistance from fire or police personnel; maintain your own situational awareness of the scene from the beginning to the end of the call.

If the patient’s injury is the result of an assault, be aware that the assailant may still be present. Make radio contact with on-scene law enforcement officers, and do not enter the scene until they state that it is safe to do so.

Primary Survey

As you begin your primary survey of a patient with a head injury, ensure manual stabilization of the cervical spine in a neutral, in-line position. With the head and neck in a neutral position through manual stabilization, identify the level of responsiveness and conduct your primary survey. You may apply a cervical collar during the primary survey if your findings require it. However, take care not to skip elements of the airway, breathing, and circulation when sizing and applying a cervical collar. Avoid moving the neck unnecessarily and continue manual stabilization until you determine SMR is not indicated, or, if indicated, SMR has been applied. Application of the cervical collar is considered a treatment intervention. Failure to assess pulse, motor, and sensory function (PMS) prior to application of this medical device could potentially alter your baseline assessment. There is no way for you to know if neurovascular compromise was present prior to your intervention or if you, in fact, worsened the patient’s injury. (See Chapter 10, *Patient Assessment*, for more information on conducting the primary survey.)

Words of Wisdom

Any patient with substantial head injury is presumed to have a spinal column injury until proven otherwise.

Prior to measuring the patient for proper cervical collar size, the cervical and thoracic spine must be in a neutral position. If the patient is seated with a slouching posture, then cervical collar measurement may be inaccurate, which may not be noticed until the patient has been transferred to the backboard.

As always, the primary survey should focus on identifying and managing life-threatening concerns. Life-threatening external hemorrhaging must be treated before airway and breathing concerns; follow the XABCDE mnemonic.

It is especially important to evaluate and monitor the level of consciousness in patients with suspected head injuries, paying particular attention to any changes that may occur. As you proceed with your assessment, ask yourself these questions: Is the patient’s speech clear and appropriate? Is the patient logical and rational? Is the patient oriented to person, place, and time? Is the patient alert to person, place, time, and why you are at the scene? Can the patient recall the events leading up to the incident or is there a period of memory lapse? Can the patient recall major current events? Use the AVPU scale (Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive) to assess the patient’s level of consciousness, and record the time.

If the patient is responsive, make sure you ask about the MOI and about any symptoms. Confused or slurred speech, repetitive questioning, or amnesia in responsive patients is a good indication of a head injury. Whereas other problems may cause similar symptoms, in the setting of trauma, assume your patient has a head injury until your assessment proves otherwise.

Reevaluate the patient and record your observations every 15 minutes if the patient’s condition is stable and at least every 5 minutes if the patient’s condition is unstable, until you reach the hospital.

If the patient is found unresponsive, emergency responders, family members, or bystanders may have helpful information, including knowledge of when the patient became unresponsive or what the previous level of consciousness was. Unresponsive patients with any trauma should be assumed to have a spinal injury. Patients with a decreased level of responsiveness on the AVPU scale (responds to verbal stimulus or responds to painful stimulus) should also be considered to have a spinal injury based on the chief complaint.

Unless the patient is absolutely clear in terms of thought processes (ie, reliable), free of intoxication secondary to alcohol or other drugs, and does not have any other illnesses or injuries that may constitute a distraction, an MOI that suggests a potential spine injury should lead you to provide SMR. Most jurisdictions have moved away from immobilizing patients based on MOI alone. Understand and follow your local protocols.

Airway Management in Patients With Head or Spine Injury

While you are maintaining the head and neck in neutral alignment, clear the mouth and carefully but quickly suction if necessary. Patients with a head injury often vomit (especially children). Therefore, after opening the airway, you must be prepared to roll the patient to the side—while maintaining SMR—to prevent aspiration. If it is safe to do so, manually remove any large debris from the patient's mouth by sweeping the oropharynx with your gloved finger. Use suction to clear secretions, such as blood or thin secretions from the oropharynx. *Mortality increases substantially if aspiration occurs.*

Open the airway with the jaw-thrust maneuver if the patient is unresponsive or is otherwise unable to maintain a patent airway spontaneously (**FIGURE 30-26**). If this technique is successful, insert an oropharyngeal airway or a nasopharyngeal airway as appropriate. An intact gag reflex is a contraindication for an oropharyngeal airway because vomiting will increase the likelihood of airway compromise and increase the risk of aspiration.

The decision to use an oropharyngeal or nasopharyngeal airway is based on the patient's ability to maintain a patent airway, the presence of a gag reflex, and the extent of facial injuries. A nasopharyngeal airway should not be used if a basilar skull fracture is suspected or if there is nasal trauma. Review the indications and contraindications for these airway adjuncts in Chapter 11, *Airway Management*.

Be sure to monitor the airway closely and have a suctioning unit available because you will often need to clear away blood, saliva, or vomitus. With large amounts of emesis, the patient may need to be log rolled to the side and the mouth swept of secretions. When it is necessary to log roll the patient to clear the airway, roll the patient while keeping the body in as straight a line as possible to restrict

YOU are the Provider

Part 3

As soon as the patient is loaded into the ambulance, you obtain a baseline set of vital signs, which lead you to suspect increased ICP. Recognizing the seriousness of the patient's injuries, you establish an 18-gauge intravenous (IV) line with normal saline to keep the vein open, and initiate rapid transport to the ED. While en route to the hospital, your patient becomes unresponsive with episodes of apnea. You recalculate his GCS and determine it to be a 3. He is unresponsive (1), with no verbal (1) or motor (1) function.

Recording Time: 8 Minutes

Respirations	26 breaths/min, Cheyne-Stokes pattern
Pulse	42 beats/min
Skin	Warm and dry
Blood pressure	216/148 mm Hg
Oxygen saturation (SpO₂)	99% on 15 L/min via nonrebreathing mask
Pupils	Pupils Equal, Round, and Reactive to Light

- On the basis of your examination findings, what degree of elevated ICP does he have?
- If this patient was unable to maintain his airway, at what rate would you initially ventilate using a bag-mask device?

A

B

unnecessary spinal motion. Suctioning should be performed immediately to remove smaller amounts of secretions.

Ventilation in the Context of Head or Spine Injury

Evaluate the patient's breathing, noting the rate, depth, and symmetry of each respiration. If an SCI has paralyzed the intercostal muscles, the patient will exhibit abdominal breathing (pure use of the diaphragm to expand the chest) and may also use accessory muscles of the neck to breathe. Closely monitor the patient's oxygen saturation (SpO_2), and maintain it at 95% or higher. Remember to consider factors such as blood loss anemia that can cause oxygen saturation levels to be falsely elevated when interpreting pulse oximetry results. Cerebral edema and ICP are aggravated by hypoxia and hypercapnia; therefore, you must constantly ensure

TABLE 30-4 Signs of Cerebral Herniation

Unresponsive patient with two or more of the following:

- Asymmetric (unequal) pupils or bilaterally fixed and dilated pupils
- Extensor posturing or no motor response to physical stimuli
- Original GCS score of less than 9 that decreases by 2 or more points from the patient's best score

Abbreviation: GCS, Glasgow Coma Scale

© Jones & Bartlett Learning.

adequate oxygenation and ventilation in any patient with a head injury. Administer 100% oxygen via a nonrebreathing mask if the patient is breathing adequately (ie, adequate rate and depth [tidal volume], regular respiratory pattern). An injured brain is even less tolerant of hypoxia than a healthy one, and research has demonstrated that even brief periods of hypoxia are associated with increases in mortality.

If the respiratory center of the brain (pons, medulla) has been injured, the rate, depth, or regularity of breathing may be ineffective. Ventilation may also be impaired by concomitant chest injuries or, if the spinal cord is injured, by paralysis of some or all of the respiratory muscles. Patients with inadequate ventilation, especially if associated with a decreased level of consciousness, should receive bag-mask ventilation and 100% oxygen. Ventilate an adult with a brain injury at a rate of 10 to 12 breaths/min or as determined by local protocols. *Avoid hyperventilation of patients with a brain injury.* Hyperventilation causes cerebral vasoconstriction, which will shunt blood from the cranium and lower cerebral perfusion. The BTF recommends hyperventilation (20 breaths/min for adults) *only* if signs of cerebral herniation are present (**TABLE 30-4**), because brief periods of hyperventilation may be beneficial. If available, ETCO_2 should be monitored with digital capnometry. You should ventilate the patient to maintain the ETCO_2 —an approximation of arterial partial pressure of carbon dioxide (PaCO_2)—between 30 and 35 mm Hg.^{21,22} Under no circumstances should the ETCO_2 be allowed to ever drop below 25 mm Hg because the subsequent vasoconstriction will increase the risk of brain death due to anoxia and cerebral ischemia.²¹

Words of Wisdom

When you assess and manage an adult with a severe head injury, remember the BTF's "90-90-9 rule".^{6,23}

1. A *single* drop in the patient's oxygen saturation to less than 90% doubles the chance of death.^a
2. A *single* drop in the patient's systolic blood pressure to less than 90 mm Hg substantially increases the chance of death.^a
3. A *single* drop of 2 points or more in the patient's prior best GCS score of less than 9 increases the chance of death.

^aThe chance of death increases exponentially if both hypoxemia and hypotension occur compared with occurrences of only one of these conditions.

Words of Wisdom

Inadequate respirations with or without evidence of decreased oxygenation will require assisted ventilation with a bag-mask device with 12 to 15 L/min of supplementary oxygen flowing at 10 to 12 breaths/min. If a head injury is suspected but you do not suspect brain herniation, use ETCO₂ monitoring to maintain CO₂ levels at 35 to 45 mm Hg.

Circulation and Volume Resuscitation in a Patient With Head or Spine Injury

In the absence of a pulse, immediately initiate cardiopulmonary resuscitation (CPR). Control any external bleeding with direct pressure or pressure dressings. Active bleeding will cause or worsen hypoxia, as well as decrease CPP, by reducing the number of oxygen-carrying red blood cells. Volume resuscitation may be necessary in patients with absent or diminished pulses, especially if the patient has multisystem trauma with hypovolemic shock.

Assess radial pulses for presence, rate, quality, and regularity. A pulse that is too slow in the setting of a head injury can indicate a serious condition. Evaluate skin color, temperature, and moisture. Patients with substantial sensory loss from SCI may equilibrate to the surrounding environmental temperature because of the lack of input from the

periphery for temperature control. In neurogenic shock, the skin is usually warm, dry, and flushed due to vasodilation and the absence of sweating. These findings should be correlated with the patient's mental status.

A single episode of hypoperfusion in a patient with a head injury can result in substantial brain damage and even death. Assess for signs and symptoms of shock and treat appropriately. Volume resuscitation may be necessary in patients with absent or diminished pulses, especially in patients with multisystem trauma with hypovolemic shock. The skull does not have enough room to accommodate large volumes of blood. As a result, an isolated closed head injury will not cause hypovolemic shock in an adult. If signs of shock are present (ie, persistent hypotension, tachycardia, diaphoresis), then carefully assess the patient for occult injuries, such as intra-abdominal or intrathoracic hemorrhage.

Special Populations

Infants may lose enough blood into the skull region to produce shock, but this is not the case with the older child or the adult patient. Provide oxygen, monitor the airway, treat for shock, and provide immediate transport. A common response to head injuries, even among children with only very slight head injuries, is vomiting. This is sometimes the result of increased ICP. In managing such vomiting, you should pay particular attention to protecting the patient's airway.

Early in the primary survey, you must decide whether to complete the secondary assessment on scene or to transport the patient immediately with interventions en route. The unstable or potentially unstable patient should be transported as soon as possible to the most appropriate hospital per local trauma guidelines or online medical control instruction.

Prompt transport to a definitive care facility (ie, a trauma center) is crucial to the survival of a patient with a brain injury. If available, consider air transport if your transport time will be prolonged. If you are transporting the patient by ground, do so expeditiously, yet cautiously.

Many patients with severe brain injuries and increased ICP require neurosurgical intervention. The extra time it takes to move the patient from one hospital to another could mean the difference between life and death. Therefore, consider transporting the patient *directly* to a trauma center that has neurosurgical services, even if it means bypassing the nearest hospital. As always, be aware of and follow local protocols.

During transport, maintaining a patent airway and providing high-flow oxygen are paramount. In supine patients, the head should be elevated 30° to help reduce ICP if possible. Remember to maintain SMR in doing this.

Offer psychological support for patients who are alert and aware of the inability to move their limbs. It can be very traumatizing for patients to realize they may now have a debilitating and life-altering injury.

History Taking

After the life threats have been managed during the primary survey, investigate the chief complaint. You should obtain a medical history and be alert for injury-specific signs and symptoms as well as any pertinent negatives such as no pain or no loss of sensation.

Using OPQRST (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing) may provide some background on isolated extremity injuries. Does the patient have any recall of the incident? Inability to recall events is an important finding in patients with head injuries. You have the opportunity to interview the patient well in advance of the emergency physician. Any information you receive will be valuable if the patient becomes unresponsive.

If the patient is not responsive, attempt to obtain the history from other sources, such as friends or family members. Medical identification jewelry and cards in wallets may also provide information about the patient's medical history. Does the patient have a recent or previous history of unresponsiveness? These key indicators may lead you to suspect a developing TBI.

Make every attempt to obtain a SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history from your

patient. History may be difficult to obtain when a person is confused from a head injury or frightened from a spinal injury. While the prehospital environment is an excellent place to obtain important history, do not delay rapid transport for patients who need rapid hospital intervention. Gather as much SAMPLE history as you can while preparing for transport.

Words of Wisdom

Can the patient smile? An inability to smile is a sign that a cranial nerve may be injured. Part the patient's hair and inspect the scalp for bruising. Look for blood or CSF leaking from the ears, nose, or mouth and for bruising around the eyes and behind the ears.

Secondary Assessment

The secondary assessment should begin with you obtaining a complete set of baseline vital signs. Modify the physical examination of any patient with suspected SCI based on the patient's level of consciousness, reliability as a historian, and MOI. In cases of high- or intermediate-risk mechanisms, complete the physical exam with the patient in a neutral position without any movement of the spine whenever possible. Apply manual stabilization while asking the patient not to move unless specifically asked to do so. The neck and trunk must not be flexed, extended, or rotated.

Depending on the chief complaint, you may focus your physical examination on the site of injury.

Patients with moderate or severe head injuries associated with a significant MOI should receive definitive care, life-saving medical or surgical intervention at the hospital, without delay. If time allows, perform a secondary assessment to identify and treat injuries that may have been missed during the primary survey en route to the ED. Extremities can be stabilized using a long backboard and splinted individually while in the back of the ambulance as time and conditions permit.

A decreased level of consciousness is the most reliable sign of TBI. Monitor the patient for changes in mental status, including signs of confusion, disorientation, anxiety, combativeness,

and deteriorating mental status. Is the patient unresponsive or repeating questions? Experiencing seizures? Nauseated or vomiting?

Although you cannot quantify ICP (ie, you cannot assign a numeric value) in the prehospital setting, you can estimate the severity of increase based on the patient's clinical presentation. You will base important treatment decisions for patients with brain injury on the presence or absence of certain key findings: posturing, hypotension or hypertension, and abnormal pupil signs.

Perform a baseline assessment using the GCS and record the time. Obtain a baseline GCS score and frequently (at least every 5 minutes, if possible) reassess it to capture the patient's clinical progression. If your jurisdiction uses the Rapid Trauma Score (RTS), then the findings from the GCS will be used in determining the RTS value. See Chapter 10, *Patient Assessment*, and Chapter 19, *Neurologic Emergencies*, for more on the GCS, and Chapter 26, *Trauma Overview*, for a discussion of RTS.

Documentation and Communication

A single assessment of the patient's GCS score cannot reliably capture clinical progression. Obtain a baseline GCS score and frequently (at least every 5 minutes if possible) reassess it in a patient with a head injury. Document all GCS scores and the times they were obtained on the patient care report. The physician will use the neurologic assessments that you performed in the field as a baseline in determining whether the patient's condition is improving or deteriorating over time.

Document all scores and the times they were obtained on the patient care report. The physicians who treat the patient will need to know when the loss of consciousness occurred and for how long. They will want to compare their neurologic evaluation with the one you performed in the field. Always use simple, easily understood terms when reporting the level of consciousness, such as “does not remember events immediately preceding injury” or “confused about date and time.” Terms such as “dazed” have different meanings to different people and should not be used in written or verbal reports.

Special Populations

When responding to an incident involving a shaken baby, you may encounter a child with an abnormal appearance but no external signs of injury. Shaken baby syndrome occurs when a caregiver violently shakes the child, often when the child is crying inconsolably, producing a severe brain injury in the child. Given that few caregivers will admit to having hurt the child, be alert for a history that is inconsistent with the clinical picture. Note whether the child has **petechial hemorrhages**. These are pinpoint red dots in the sclera of the eye and represent the rupture of tiny vessels. This finding indicates that the baby was shaken, although this finding may not be present in every case of shaken baby syndrome. Be sure to document the presence or absence of this finding; this information could be significant if law enforcement investigates the case.

Frequently the mental status will fluctuate—improving, deteriorating, and then improving again over time. On other occasions, there is a gradual, progressive deterioration in the patient's response to stimuli; this usually indicates serious brain damage that may need aggressive medical and/or surgical treatment.

To examine the spine, you will need to expose the patient for your examination. Cut away the patient's clothes to minimize motion of the spine during examination or treatment. Directly observe the back to assess for penetrating trauma. In case of potential spine injuries, the physical exam includes rapid inspection and palpation of the head, neck, chest, abdomen, pelvis, extremities, and back for injuries. Use the mnemonic DCAP-BTLS—Deformity, Contusion, Abrasion, Puncture/penetration wounds, Bruising, Tenderness, Laceration, and Swelling—to help you remember specific points. An evaluation of neurovascular integrity should include distal PMS for all four extremities (**FIGURE 30-27**). Sensation may be present throughout the body. If there is impairment, note the level. You do not need to know the exact nerve impairment because this will not change your treatment.

Pain or tenderness when you palpate the spinal area is certainly a warning sign that a spinal injury may exist. Patients with spinal injuries may

A

B

FIGURE 30-27 **A.** Assess the equality of strength of each extremity by asking the patient to squeeze your hands. **B.** Next, ask the patient to gently push each foot against your hands.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

report constant or intermittent pain along the spinal column or in their extremities. An SCI may also produce pain independent of movement or palpation.

Evaluate the chest and abdomen for both internal and external injuries. Fractures of the ribs, sternum, clavicle, scapula, or pelvis are often associated with SCI in patients with multisystem trauma. Visualization and palpation are the mainstays of this evaluation. Remember, the physical exam in the patient with an SCI may be skewed because of decreased sensation below the level of spinal injury. Assess the chest wall visually for symmetry of chest wall movement, work of breathing, and use of accessory muscles. Auscultation to assess breath sounds may reveal a shortened inspiratory phase. Inadequate ventilation may indicate

chest musculature or diaphragmatic impairment as a result of SCI.

Also, injuries to the cervical area can limit the ability of the diaphragm to function fully and minimize the ability of the chest to expand, so continue to always pay attention to managing the airway and breathing.

Use monitoring devices to quantify your patient's oxygenation and circulatory status. If available, ETCO_2 monitoring should be used on all patients suspected of having a TBI to ensure the patient is not hypoventilating or hyperventilating. You should also monitor the blood pressure. It is recommended that you always assess the patient's first blood pressure manually with a sphygmomanometer (blood pressure cuff) and stethoscope.

Continually monitor the cardiovascular system for signs of shock. Neurogenic shock may require volume replacement or paramedic backup for pharmacologic management.

Examination of the gastrointestinal system may be unreliable in the presence of a neurologic deficit. First, inspect the abdomen for evidence of trauma, noting its contour. Severe gastric distention may impair respiration and result in airway compromise due to vomiting. Palpate all four quadrants for tenderness, guarding, or rigidity, but remember that patients may be insensitive to pain and may not develop a rigid abdomen because of absence of muscle tone. Lower abdominal distention with or without suprapubic tenderness may be a result of urinary retention. In men, assess the urethral meatus for evidence of blood, scrotal swelling, and scrotal ecchymosis, which may occur with pelvic fractures. Assess for priapism as well.

Look for any abnormal posturing, and assess the patient for potential long bone or other substantially distracting painful injuries that may mask a potential spine or cord injury.

After the exam is completed, quickly cover the patient with a blanket to maintain normal body temperature. Hypothermia will develop rapidly and will impair the patient's ability to unbind oxygen from hemoglobin and increase the risk of mortality and morbidity. In colder climates, move the patient to a warmer environment, such as the ambulance, as quickly as possible without compromising the spine further.

Words of Wisdom

Patients may experience an inability to maintain their body temperature. Always keep patients covered, even in warm weather.

Assessment Pearls

- The eyes are the windows to the brain; check the pupils!
- For suspected TBI, elevate the head of the backboard 30° (6 inches [15 cm]) to help relieve pressure. Do not sit the patient up by flexing at the waist; doing so disrupts spinal alignment and increases risk of secondary thoracolumbar SCI.
- Do not hyperventilate patients with TBI unless signs of herniation are present. Instead, ventilate adult patients at 10 breaths per minute, children at 20 breaths per minute, and infants at 25 breaths per minute to maintain an ETCO_2 of 30 to 35 mm Hg.
- If no signs of TBI are present, ventilate at normal rates to maintain ETCO_2 at 35 to 45 mm Hg.
- Gain IV access early and keep systolic pressure above 90 mm Hg for patients with TBI and signs of increased ICP.
- Pay attention to vital signs. Is the blood pressure going up while the pulse rate is dropping? Note the subtle signs of increasing ICP.
- For patients with suspected neurogenic shock, consider calling for paramedic backup for pharmacologic intervention.
- Rules of thumb for helmet removal:
 - Remove motorcycle helmets to facilitate spinal alignment.
 - Leave football helmets in place if the patient is wearing shoulder pads and the airway can be managed.
- Always take helmets to the hospital with the patient so that the helmet can be examined for areas of damage.
- Never discount the possibility of TBI or intracranial hemorrhage in a patient who appears intoxicated. Always check glucose levels and provide prompt and aggressive treatment and transport.
- Check glucose levels in patients with possible TBI prior to giving IV glucose.

Finally, if possible, use a glucometer to assess blood glucose level in patients who show evidence of alterations in sensation or mental status; an altered mental status may be the result of hypoglycemia.

Reassessment

Frequent reassessments are necessary to help you determine whether the patient is stabilizing, improving, or deteriorating. Vital signs should be monitored every 5 minutes (unstable patients) to 15 minutes (stable patients), with special attention to the patient's cardiovascular status. Be alert for hypotension without other signs of shock. The combination of hypotension with a normal or slow pulse and warm skin greatly suggests neurogenic shock. The SCI responsible for neurogenic shock also usually produces a flaccid paralysis and complete loss of sensation below the level of the injury. In contrast to neurogenic shock, hypovolemic shock is associated with pale, cold, clammy skin and tachycardia.

Check interventions such as oxygen flow and SMR to ensure that they are still effective. Repeat the physical exam and reprioritize the patient as necessary. Document suspected SCI, noting the area involved, sensation, motor function, and areas of weakness.

When providing care for patients with suspected head and spinal injuries, it is essential to maintain good communication with the destination facility. Hospitals may better prepare for seriously injured patients with more advanced warning and a description of the most serious problems found during your assessment, and additional resources can be made available when you arrive.

Your documentation should include the history you were able to obtain at the scene, your findings during your assessment, treatments you provided, and how the patient responded to them.

Words of Wisdom

The most important aspect of neurologic assessment is whether the patient's findings are changing and in what direction.

Emergency Medical Care of TBI

Remember that patients with head trauma often have injuries to the cervical spine as well. Therefore, when treating a patient with a TBI, you must keep in mind the need to protect and immobilize the cervical spine at all times.

Treat the patient with TBI according to four general principles, which are designed to protect and maintain the critical functions of the CNS:

1. Establish an adequate airway. If necessary, begin and maintain ventilation and always provide high-flow supplemental oxygen. Consult local protocols for the appropriate rate if ventilation via a bag-mask device is required.
2. Control bleeding, and provide adequate circulation to maintain cerebral perfusion. Begin CPR, if necessary. Be sure to follow standard precautions.
3. Start at least one 18-gauge IV line and administer an isotonic crystalloid solution as needed.
4. Assess the patient's baseline mental status, and continuously monitor it.

Manage the airway and provide oxygen as indicated by patient status. Ventilate an adult with a brain injury at a rate of 10 breaths/min or as determined by local protocols. Follow local protocols and medical direction regarding hyperventilation in the presence of herniation. Continue to assist ventilations or administer supplemental oxygen until the patient reaches the hospital.

As you continue to treat the patient, do not apply pressure to an open or depressed skull injury. In addition, you must assess and treat other injuries,

dress and bandage open wounds as indicated in the treatment of soft-tissue injuries, splint fractures, anticipate and manage vomiting to prevent aspiration, be prepared for seizures and changes in the patient's condition, and transport the patient promptly and with extreme care.

Shock that develops in a patient with a TBI may be the result of hypovolemia caused by bleeding from other injuries. Such patients must be transported immediately, preferably to a trauma center. Maintain the airway while you protect the patient's cervical spine, ensure adequate ventilation, administer 100% oxygen, control obvious sites of bleeding with direct pressure, place the patient supine on a long backboard, keep the patient warm, and provide immediate transport.

Establish at least one 18-gauge IV line with normal saline or lactated Ringer solution. Do not administer dextrose-containing solutions (such as 5% dextrose in water [D₅W]) because they may worsen cerebral edema. The *only* indication for administering glucose to a patient with a head injury is confirmed hypoglycemia (ie, a glucometer reading of 45 mg/dL or less).

Patients with a severe TBI are often hypertensive—a sign of the body's autoregulatory response. Restrict your use of IV fluids for these patients to minimize cerebral edema and ICP, typically at a rate of 30 to 50 mL/h.²⁴ However, if hypotension develops, infuse isotonic crystalloids as needed—usually 20-mL/kg boluses or as directed by medical control—to maintain a systolic blood pressure of above 90 mm Hg in patients with a TBI and a GCS score of less than 9.²⁵ Hypotension in a patient with a brain injury can be lethal because it may decrease the CPP, with resultant cerebral ischemia, permanent brain damage, and death. You must continuously monitor the patient's blood pressure to quickly identify any downward trend in the systolic blood pressure and respond before hypotension develops.

Do not allow the patient to become overheated. Patients with a head injury, unlike those with shock, are at risk for the development of a high body temperature (**hyperpyrexia**), which may worsen the condition of the brain. Do not cover the patient with blankets if the ambient temperature is 70°F (21°C) or higher.

If the patient has an open fracture of the skull with brain tissue oozing out, cover it lightly with a sterile dressing that has been moistened with sterile

Words of Wisdom

Effectively managing the airway of a patient with a brain injury and ensuring adequate oxygenation and ventilation are absolutely critical to the patient's survival. Of course, severe bleeding can also result in death. Therefore, you and your partner should perform airway management and bleeding control simultaneously.

saline. Likewise, for leakage of CSF from the ears or nose, apply loose, sterile dressings just to keep the area clean. Objects impaled in the skull should be stabilized in place and protected from being jarred.

Scalp Lacerations

Scalp lacerations can be minor or serious. Because both the face and the scalp have unusually rich blood supplies, even small lacerations can quickly result in substantial blood loss (**FIGURE 30-28**). Scalp lacerations alone in adults rarely cause hypovolemic shock; this result is more common in children. However, bleeding from the scalp can contribute to hypovolemia in any patient, especially one with multiple injuries.⁴ In addition, because scalp lacerations are usually the result of direct blows to the head, they often indicate deeper, more serious injuries.

You can almost always control bleeding from a scalp laceration by applying direct pressure over the wound. Remember to follow standard precautions. Use a dry sterile dressing, and fold any avulsions (torn skin flaps) back down onto the skin bed before applying pressure (**FIGURE 30-29A**). In some cases, you will have to apply firm compression for several minutes to control the bleeding (**FIGURE 30-29B**).

If you suspect a skull fracture, do not apply excessive pressure to the open wound. Excessive pressure may increase the ICP or push bone fragments into the brain.

If the dressing becomes soaked, remove it and reevaluate the area where pressure is applied. Continue applying manual pressure until the bleeding is controlled, then secure the dressing in place with a soft, self-adhering roller bandage (**FIGURE 30-29C**).

FIGURE 30-28 The scalp has an unusually rich blood supply; therefore, even small lacerations can result in substantial blood loss.

© Jones & Bartlett Learning.

YOU are the Provider

Part 4

After establishing the absence of a gag reflex, you measure and insert an appropriate-size oropharyngeal airway and begin ventilations at a rate of 10 breaths/min. You instruct your partner to contact the ED and advise them of the patient's condition and estimated time of arrival. On your arrival at the ED, you turn over care to the awaiting physician without incident.

Recording Time: 18 Minutes

Respirations	Assisted at 10 breaths/min
Pulse	44 beats/min
Skin	Warm and dry
Blood pressure	210/144 mm Hg
Oxygen saturation (SpO₂)	100% on 15 L/min
Pupils	Left pupil dilated and nonreactive

- At what point should you start hyperventilating the patient with a TBI?
- What is the appropriate type of hospital for this patient?

FIGURE 30-29 **A.** Use a dry sterile dressing to fold torn skin flaps back down onto the skin bed before applying pressure. **B.** If you do not suspect an open brain injury or skull fracture, apply firm compression for several minutes to control the bleeding. **C.** Secure the compression dressing in place with a soft, self-adhering roller bandage.

Emergency Medical Care of Spinal Injuries

Improper handling of a spinal injury can render a patient permanently paralyzed, but remember that airway management always takes priority. If a patient with a spinal injury has an airway obstruction, you should perform the jaw-thrust maneuver to open the airway, as discussed earlier. After the airway is open, hold the head still, in a neutral, in-line position, until it can be fully immobilized. Assess respirations and provide supplemental oxygen or ventilatory support as needed. Consider

inserting an oropharyngeal airway. Monitor the airway closely and have a suctioning unit available. Be prepared for any changes in the patient's condition based on your treatment.

Immobilization of the Cervical Spine

Stabilize the head and trunk so that potentially fractured bone fragments of the spine do not cause further damage. Even small movements can substantially injure the spinal cord. To perform manual in-line stabilization, follow the steps in **SKILL DRILL 30-1**.

You should never force the head into a neutral, in-line position. Do not move the head any farther if the patient reports any of the following symptoms:

- Muscle spasms in the neck
- Increased pain with movement
- Numbness, tingling, or weakness in the arms or legs
- Compromised airway or ventilations

In these situations, immobilize the patient in their current position.

Cervical Collars

Rigid cervical immobilization devices, or cervical collars, provide preliminary, partial support. A cervical collar should be applied to every patient who has a possible spinal injury based on MOI, history, or signs and symptoms. Keep in mind, however, that cervical collars do not fully immobilize the cervical spine and do nothing to help stabilize the thoracic or lumbar spine. Therefore, you must be vigilant to avoid moving the cervical spine during patient transfers and supplement the immobilization using another SMR device, such as backboard or vacuum mattress when indicated.

To be effective, a rigid cervical collar must be the correct size for the patient. It should rest on the shoulder girdle and provide firm support under both sides of the mandible, without obstructing the airway or ventilation efforts in any way (**FIGURE 30-30**). If you do not have an appropriate-size cervical collar, you may use a rolled towel around the patient's head. Tape the patient's head along with the towel to the backboard

Skill Drill 30-1 Performing Manual In-Line Stabilization

Step 1

Take standard precautions. Begin by holding or having someone firmly hold the head with both hands. Whenever possible, kneel at the head of the patient, and place your hands around the base of the skull on either side.

Step 2

Support the lower jaw with your index and long fingers, while you are supporting the head with your palms. Gently lift the head until the patient's eyes are looking straight ahead and the head and torso are in line. This neutral, eyes-forward position makes immobilization easier. Align the nose with the navel. Do not move the head or neck excessively, forcefully, or rapidly.

Step 3

Manually maintain this position while your partner places a rigid cervical collar around the neck to provide more stability. Do not remove your hands from the patient's head until the patient's torso and head have been secured to a backboard or other appropriate device. The patient must remain immobilized until an examination at the hospital has been completed.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

or vacuum mattress and provide supplemental continuous manual support (**FIGURE 30-31**).

To apply a cervical collar, follow the steps in **SKILL DRILL 30-2**.

After the patient's head and neck have been manually stabilized, assess the PMS in all extremities. Then assess the cervical spine area and neck.

Keep in mind that the cervical collar is used to provide increased stability to the neck. It is used in addition to, not instead of, manual cervical stabilization. An improperly fitting collar can do more harm than good. In any case, maintain manual support until the patient has been fully secured to the backboard or other appropriate immobilization device.

Words of Wisdom

Remember, applying a cervical collar is not the equivalent of performing SMR; it is a component that contributes to immobilization.

FIGURE 30-30 Proper fit is essential in applying a cervical collar. The collar should rest on the shoulder girdle and provide firm support under both sides of the mandible without obstructing the airway or any ventilation efforts.

© Jones & Bartlett Learning.

Preparation for Transport

There are several types of long backboard immobilization devices that provide full-body immobilization (**FIGURE 30-32**). They also provide stabilization and immobilization to the head, neck, torso, pelvis, and extremities. Long backboards can be used to immobilize patients who are found in any position

FIGURE 30-31 If you do not have an appropriate-size cervical collar, you may use a rolled towel around the patient's head. Tape the patient's head along with the towel to the backboard or vacuum mattress and provide supplemental continuous manual support.

© Jones & Bartlett Learning.

Skill Drill 30-2 Application of a Cervical Collar**Step 1**

One AEMT provides continuous manual in-line support of the head while the other prepares the collar.

**Step 2**

Measure the proper collar size according to the manufacturer's specifications. It is essential that the cervical collar fits properly.

Skill Drill 30-2 Application of a Cervical Collar (continued)

Step 3

Place the chin support snugly underneath the chin.

Step 4

Maintaining head stabilization and neutral neck alignment, wrap the collar around the neck, and secure the collar to the far side of the chin support.

Step 5

Ensure that the collar fits properly and recheck that the patient is in a neutral, in-line position. Maintain in-line stabilization until the patient is secured to a backboard or other appropriate device.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

(prone, sitting, supine), sometimes in conjunction with short backboards.

Common short immobilization devices are the vest-type (**FIGURE 30-33**) and the rigid short board. These devices are designed to stabilize and immobilize the head, neck, and torso. They are used to immobilize patients in noncritical condition who are found in a sitting position and have possible spinal injuries.

Supine Patients

A patient who is supine can be effectively immobilized on a long backboard. The ideal procedure for moving a patient from the ground to a backboard

is the **four-person log roll**. This procedure is recommended any time you suspect a spinal injury. In other cases, you may choose instead to slide the patient onto a backboard or use a scoop stretcher. The patient's condition, the scene, and the available resources will determine the method you choose.

You should first take the necessary standard precautions and then direct the team from a kneeling position by the patient's head so that you can maintain manual in-line stabilization. Your job is to ensure that the head, torso, and pelvis move as a unit, with your teammates controlling the movement of the body. If necessary, you may recruit bystanders to the team, but be sure to instruct them fully before moving the patient. To secure

FIGURE 30-32 Long backboard immobilization devices allow for full-body immobilization, including stabilization of the head, neck, torso, pelvis, and extremities.

Controversies

The Evolution of Spinal Care

SMR is a controversial topic in prehospital medicine. It has been one of the most common procedures used in EMS for decades because injury to the spinal cord, especially high-level injury, is life threatening and can devastate the patient's quality of life.²⁶

Potential Negatives of Backboarding

It is important to remember that actions or inactions in the prehospital setting have direct consequences for the patient and the receiving facility. One study found that when immobilization procedures are used, patients spend an average total time of 54 minutes on the backboard, with 33 of those minutes, on average, spent in EMS care and 21 minutes spent in the ED.²⁷

Hyperextension of the cervical spine that can occur during immobilization procedures can cause neurologic deficits. Therefore, you must immobilize the patient in a neutral position. The adult patient requires 0.5 to 2 inches (1.25 to 5 cm) of padding behind the occiput to achieve a neutral position.²⁸ Immobilizing the patient's head directly on the backboard produces hyperextension of the cervical spine, thereby increasing the risk of neurologic deficit.

In patients immobilized for a prolonged time, pain also often develops in the occipital, sacral, and lumbar areas secondary to pressure on these areas. This can result in potentially unnecessary radiographic studies being ordered, and even longer times on the backboard.²⁹ Padding in the lumbar region and under the patient's knees, to keep the legs slightly flexed, can reduce pain in the lumbar and sacral areas. A vacuum mattress, as compared to a backboard, has been shown to reduce pain and neurologic deficit.

Other complications include ulcers and pressure sores, increased risk of aspiration, and respiratory compromise, although these complications are rare. Cervical collars that are applied too tightly and not reassessed for proper fit can raise ICP.³⁰ TBI is common in trauma, and increased ICP is associated with worse neurologic outcomes. Finally, airway management is more difficult with a cervical collar than without.

Evidence-Based Medicine

Prior practice was to immobilize everyone.^{31,32} Publications and position statements have advocated for avoiding immobilization in a subset of patients for whom there is little potential benefit and for whom

the discomfort of immobilization, the time to achieve immobilization, and the potential complications of immobilization exceed any potential advantage—in short, those for whom the risk of immobilization outweighs any potential benefits.³³

Indications for cervical spine immobilization are listed in **TABLE 30-5**. Much of the impetus for change has revolved around three concerns: (1) discomfort and risk of skin breakdown associated with immobilization on a hard backboard, (2) decreased ability for a patient to maintain airway patency when thoroughly immobilized, and (3) increased scene time associated with the immobilization process.³⁴⁻³⁷

An argument against immobilization has also been that it is relatively ineffective. The use of the term spinal motion *restriction* reflects this argument. It is true that SMR results in incomplete immobilization of the spine. It is also true that immobilization of a femur in a traction splint or immobilization of a tibia in a leg splint results in incomplete immobilization. That does not make it ineffective or otherwise useless. The purpose of SMR is to prevent secondary damage to the spinal cord, not to completely immobilize the spine and prevent micromotion at the site of any injury.

The published protocols (including those of the American College of Surgeons Committee on Trauma, National Association of EMS Physicians, and others) make good common sense. Patients with a low likelihood of injury based on either low-risk mechanism (eg, gunshot wounds) or reliable physical exam do not need to be immobilized. Unfortunately, trends toward decreasing the frequency of immobilization tend to flow past logic and evidence. In some cases, aggressive and potentially dangerous practices are being implemented, in which immobilization of the spine is effectively eliminated from EMS protocols and cervical collars are applied with no further immobilization of the spine instituted or even attempted. In some cases, careful processes and procedures are employed in the process of transferring patients in lieu of the traditional backboard and collar packaging. It is important to remember that the reason SMR emerged initially as a tool in EMS was that there were reported cases of patients in whom a progression of neurologic deficits developed during the course of medical care and transport in the absence of immobilization, and recognition of the potential for unstable spinal column injury.³⁸ We will

likely never be able to know if any of those patients' neurologic injuries could have been prevented with better immobilization. The protocols and practices that followed involving the boarding and collaring of all patients with a suspicious MOI, regardless of other signs or symptoms, likely represented unnecessary treatment and may have actually resulted in some degree of harm to a few patients and some degree of discomfort to many. Although the risk of causing an unstable spinal injury in a neurologically uninjured or only partially injured patient to progress to a devastating neurologic consequence is clearly low, it remains the reason we employ SMR and other precautionary techniques in this patient population. A backboard and collar remind everyone who comes in contact with the patient that there is an unresolved question as to the presence of injury and stability of the spinal column and therefore a potential ongoing risk to the integrity of the patient's spinal cord. Failing to immobilize with a backboard and collar removes that reminder from the view of those who are not necessarily familiar with the history, MOI, or specific symptoms.

It is definitely possible to move a patient safely without use of a backboard, but it is also possible that someone will not think about the need to employ spinal precautions during a transfer and move the patient in a way that will result in permanent devastating neurologic injury. Use of a backboard and collar decreases that risk by increasing the awareness of everyone who comes in contact with the patient. It is also important to consider that between the time a patient is extricated from a vehicle and arrival in the ED, the number of times the patient is passively moved, and the forces associated with those moves, are much greater than after arrival at the hospital. Compared to the response scene or even the back of the ambulance, the hospital is a much more controlled environment. Simply put, it is safe to remove the backboard and collar in the ED, but it may not be safe to avoid applying it altogether in high-risk patients.³⁹

Remember: "first do no harm." You certainly do not want to cause injury or even unnecessary discomfort to someone when immobilization is not necessary. But you really do not want to cause or even contribute to a permanent paraplegia or quadriplegia in someone who sustained a fracture or dislocation and had intact neurologic function prior to your involvement.

a patient to a long backboard, follow the steps in **SKILL DRILL 30-3**.

Patients found in a prone or semiprone position must be placed in a supine position to assess

airway, breathing, and circulation and to properly immobilize the spine. One rescuer should take control of the cervical spine using a crossed-hand position to roll the patient. The second rescuer should

TABLE 30-5 Indications for Cervical Spine Immobilization

- Appropriate patients for backboard use may include those with any of the following:
 - Blunt trauma and altered level of consciousness
 - Spinal pain or tenderness
 - Neurologic complaint (eg, numbness or motor weakness)
 - Anatomic deformity of the spine
 - High-energy MOI and any of the following:
 - Drug or alcohol intoxication
 - Inability to communicate
 - Distracting injury
- Patients for whom immobilization on a backboard is not necessary include those with all of the following:
 - Normal level of consciousness (GCS score of 15)
 - No spine tenderness or anatomic abnormality
 - No neurologic findings or complaints
 - No distracting injury
 - No intoxication
- You can maintain a degree of SMR by applying a rigid cervical collar and securing the patient to the EMS stretcher without a backboard. These measures are most appropriate for:
 - Patients who are ambulatory at the scene
 - Patients who must be transported for a long time, particularly before interfacility transfer
 - Patients for whom a backboard is not otherwise indicated
- Patients with penetrating trauma to the head, neck, or torso and no evidence of spinal injury should not be immobilized to a backboard.

Abbreviations: GCS, Glasgow Coma Scale; MOI, mechanism of injury

Data source: National Association of EMS Physicians Position Statement. EMS spinal precautions and the use of the long backboard. *Prehosp Emerg Care*. 2013;17(3):392-393.

Skill Drill 30-3 Performing SMR of a Supine Adult Patient

Step 1

Take standard precautions. Apply and maintain manual in-line stabilization at the patient's head, as previously discussed.

Step 2

Assess distal PMS in each extremity.

Skill Drill 30-3 Performing SMR of a Supine Adult Patient (continued)

Step 3

Apply a well-fitting cervical collar as previously discussed.

Step 4

Rescuers position the backboard or immobilization device beside the patient, kneeling on one side of the patient and placing their hands on the far side of the patient to increase their leverage. Rescuers use their body weight, shoulders, and back muscles to ensure a smooth, coordinated pull. The pull should concentrate on the heavier portions of the body.

Step 5

On count/command of the person holding manual in-line stabilization, rescuers roll the patient toward themselves. This rolling technique prevents the patient from twisting. One rescuer should quickly examine the back while the patient is rolled onto the side, then slide the backboard behind and under the patient. The team should then roll the patient onto the backboard, avoiding rotation of the head, shoulders, and pelvis.

Step 6

Center the patient on the board with no lateral movement.

(continues)

Skill Drill 30-3 Performing SMR of a Supine Adult Patient (*continued*)

Step 7

Apply padding as necessary to fill the voids between the patient and the device. When possible, prepare blanket rolls ahead of time and have them ready to go. When you have the blankets prepared, you need only seconds to place them.

Step 8

Secure the upper torso to the backboard.

Step 9

Secure the pelvis and upper legs, using padding as needed. For the pelvis, use straps over the iliac crests and/or groin loops (leg straps).

Step 10

Pad behind the patient's neck and head area as needed to maintain a neutral in-line position.

Skill Drill 30-3 Performing SMR of a Supine Adult Patient (continued)

Step 11

Immobilize the head to the backboard with a commercial immobilization device per the manufacturer's instructions. Alternatively, rolled towels may be used. Secure the head to the backboard only after the entire torso has been secured. If the head is secured first and the body shifts, the spine may be compromised. Securing most of the body weight first creates better protection.

Step 12

Secure the patient's lower legs to the backboard.

Step 13

Secure the patient's arms with a single strap.

Step 14

Check and readjust straps as needed to ensure the entire body is snugly secured and will not slide during movement of the backboard or during patient transport. Reassess distal PMS in each extremity and repeat periodically.

be positioned at the torso, with any additional help at the pelvis and legs. The rescuer at the head counts, and the patient should be rolled as a unit into a supine position. Assessment and immobilization should then continue as usual.

Special Populations

As the disks between the vertebrae begin to narrow, or wear out, a decrease in height of between 2 and 3 inches (5 and 8 cm) may occur overall throughout a person's life span. A decrease in the amount of muscle mass often results in less strength, and fractures are more likely to occur because of a decrease in bone density (osteoporosis). Posture also changes as an anterior curling of the shoulders produce a condition called kyphosis (also called humpback or hunchback), making immobilization of older persons more challenging.

To immobilize kyphotic patients, several blankets and pillows or a vacuum mattress may be required to provide support to the head and upper back. Make sure that the empty spaces under the patient's knees or lumbar spine are padded as well.

Words of Wisdom

Make sure that everyone is clear on the count before moving a patient. Will the count be 1, 2, 3, roll, or will the roll be performed *on* 3?

An alternative to the long backboard is the scoop stretcher. **SKILL DRILL 30-4** summarizes how to immobilize a patient using a scoop stretcher.

Another alternative to the long backboard is to place the patient on a vacuum mattress. The vacuum mattress molds to the specific contours of the patient's body, reducing pressure point tenderness and therefore providing better comfort. The mattress also provides thermal insulation, potentially decreasing the risk of hypothermia, and is the standard equipment used to transport patients with spinal injuries in the United Kingdom. It is an excellent alternative to a backboard for older adults or patients with abnormal curvature of the spine. A drawback to the device is its thickness, requiring careful patient movement to maintain SMR during

Skill Drill 30-4 Using a Scoop Stretcher

Step 1

With the scoop stretcher separated, measure the length of the scoop and adjust to the proper length.

Step 2

Position the stretcher, one side at a time. Lift the patient's side slightly by pulling on the far hip and upper arm, while your partner slides the stretcher into place.

Skill Drill 30-4 Using a Scoop Stretcher (continued)

Step 3

Lock the stretcher ends together by engaging their locking mechanisms one at a time, and continue to lift the patient slightly as needed to avoid pinching the patient or your fingers.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 4

Apply and tighten straps to secure the patient to the scoop stretcher before transferring to the stretcher.

the application procedure. The vacuum mattress cannot be used for patients who weigh more than 350 pounds (159 kg).

As with a backboard, a vacuum mattress can be used on a supine or sitting patient.

A patient can be moved onto the vacuum mattress with a scoop stretcher or a log roll. For the scoop stretcher method, the mattress does not need to be partially rigid.

It is important to secure the patient sufficiently but without restricting the patient's breathing. If the patient is not secured sufficiently, this can cause excessive movement, increasing the risk of subsequent SCI. Follow the steps in **SKILL DRILL 30-5** to immobilize a patient with a vacuum mattress.

Seated Patients

Some patients with a possible spinal injury will be in a sitting position, such as after an automobile crash, and reporting only isolated neck or back pain. With these patients, you should use a short backboard or a vest-style spinal extrication device to immobilize the cervical and thoracic spine. The

short immobilization device is then secured to a long board. These short SMR devices should be used only with patients who are *stable* and do not require rapid extrication.

Special Populations

Osteoporosis in the thoracic and lumbar spine contributes to a high rate of injury in older patients. Three types of fractures are commonly encountered in the geriatric age group:

- **Compression fractures**—stable injuries that often result from minimal trauma, such as simply bending over, rising from a chair, or sitting down forcefully.
- **Burst fractures**—unstable fractures that typically result from a high-energy MOI such as a motor vehicle crash or a fall from substantial height.
- **Seat belt-type fractures**—involve flexion and cause a fracture through the entire vertebral body and bony arch. These injuries typically result from an ejection or in people who are wearing only a lap belt without a shoulder harness.

Skill Drill 30-5 Placing a Patient on a Full-Body Vacuum Mattress

Step 1

Place the mattress on a flat surface near the patient. Make sure the head end of the mattress is at the patient's head.

Step 2

Allow air to enter the mattress. Keep the valve stem open until the mattress is soft and pliable.

Step 3

Smooth the mattress so that it is flat and level. Remove any sharp or bulky items that may damage the mattress.

Step 4

Connect the pump to the mattress.

A

B

Step 5

Determine which method you will use to move the patient onto the mattress. If you use the log roll method (**A**), evacuate the mattress until it is partially rigid. (This step is not needed if using the scoop stretcher method [**B**]). The surface should be smooth and the beads should be spread out as evenly as possible.

Skill Drill 30-5 Placing a Patient on a Full-Body Vacuum Mattress (continued)

Step 6

Move the patient onto the vacuum mattress using one of the two methods: scoop stretcher or log roll. Throughout this procedure, maintain spinal alignment.

For the scoop stretcher method, the mattress does not need to be partially rigid:

- Apply the scoop stretcher to the patient, then lift and transfer the patient onto the mattress.
- Position the patient so the head is in the head area of the mattress or very close to the mattress's top edge.
- Remove the scoop stretcher from around the patient and proceed with application of the vacuum mattress.

For the log roll method, the mattress should be partially rigid:

- Place the mattress on a backboard or transfer device.
- Hold the mattress in place on the backboard, and log roll the patient onto the backboard with the mattress on top of it. (The long backboard is used only for stabilization.)
- Position the patient so the head is very close to the top edge.

Step 7

If the vacuum mattress is partially rigid, open the valve to allow air to enter. Keep the valve open until the mattress is pliable.

Step 8

Conform the mattress to each side of the patient's head, close to the shoulders but not the top of the head. Continue to hold these "head blocks" that you have formed, and have a second person hold up the sides of the mattress to the patient's hips until the mattress is evacuated of air completely. Always form the mattress to meet the needs of the patient. Use additional rescuers if needed. Some patients may be more comfortable with their knees slightly bent.

(continues)

Skill Drill 30-5 Placing a Patient on a Full-Body Vacuum Mattress (continued)

Step 9

Secure the patient's chest, hips, and legs in the mattress.

Step 10

Secure the patient's head with medical tape. Pad any voids at the top of the shoulders.

Step 11

Ensure the patient is as comfortable as possible, then evacuate the remaining air to achieve immobilization. (A portable suction unit can be used to evacuate some mattresses; see manufacturer recommendations.)

Step 12

Disconnect the vacuum pump and ensure that the valve is closed or secured so the mattress is not accidentally deflated.

Step 13

Reassess and adjust the straps around the chest, hips, and legs.

Step 14

Check the patient's neurovascular status and recheck all straps prior to lifting or moving the patient.

Special Populations

When you are immobilizing a pregnant patient, tilt the backboard 15° to 20° to the left using a pillow or blankets if the size of the gravid uterus is enough to weigh heavily on the inferior vena cava or for patient comfort. If this is not possible, manually displace the uterus to the left side.

The exceptions to this rule are situations in which you do not have time to first secure the patient to the short board, including the following situations:

- You or the patient is in danger.
- You need to gain immediate access to other patients.
- The patient's injuries justify urgent removal.

In these situations, your team should lower the patient directly onto a long backboard, using the rapid extrication technique. Be sure that you provide manual stabilization of the cervical spine as you move the patient. Rapid extrication is indicated only in cases of life- or limb-threatening injury. In all other cases, follow the steps in **SKILL DRILL 30-6** to immobilize a sitting patient. The rapid extrication technique is described in more detail in Chapter 6, *Lifting and Moving Patients*.

Words of Wisdom

Ask the patient to take a deep breath before tightening the torso straps. This will ensure that breathing is not impeded by the device.

Skill Drill 30-6 Performing Immobilization of a Seated Adult Patient

NR Skill

Step 1

Take standard precautions and direct another rescuer to place and maintain manual in-line stabilization of the patient's head and neck. Evaluate the patient's reliability as a historian. Assess distal PMS in each extremity.

Apply a proper-size cervical collar. Because the cervical collar does not completely immobilize the cervical spine, continue manual stabilization of the head and neck until the patient is fully immobilized and secured on a backboard.

Step 2

Insert the immobilization device between the patient's upper back and the seat back.

(continues)

Skill Drill 30-6 Performing Immobilization of a Seated Adult Patient (*continued*)

Step 3

Open the device's side flaps (if present) and position them around the patient's torso, snug under the armpits.

Step 4

When the device is properly positioned, secure the upper torso straps.

Step 5

Position and fasten both groin loops (leg straps). Pad the groin as needed. Check all torso straps and make sure they are secure. Make any necessary adjustments without excessively moving the patient.

Step 6

Pad any space between the patient's head and the device. Secure the forehead strap or tape the head securely and then fasten the lower head strap around the cervical collar. Reevaluate the patient to ensure adequate immobilization. Reassess distal PMS in each extremity.

Skill Drill 30-6 Performing Immobilization of a Seated Adult Patient (*continued*)

Step 7

Place a long backboard next to the patient's buttocks, perpendicular to the trunk.

Step 8

Turn the patient parallel to the long backboard, and then slowly lower the patient onto it. Lift the patient and the vest-type board together as a unit (without rotating the patient), and slip the long backboard under the patient and the immobilization device. Slide the patient onto the backboard as a unit using any handles that may be built into the device. Release the leg straps and loosen the chest strap to allow the legs to straighten and give the chest room to fully expand.

Step 9

Secure the device and the long backboard together. Do not remove the vest-type board from the patient. Reassess distal pulse and motor and sensory function in each extremity. Note your findings on the patient care report and prepare for transport.

Patients Wearing Helmets

As you plan your care of a patient wearing a helmet, ask yourself the following questions:

- Is the patient's airway clear?
- Is the patient breathing adequately?
- Can you maintain the airway and assist ventilation if the helmet remains in place?
- Can the face guard be easily removed to allow access to the airway without removing the helmet?
- How well does the helmet fit?
- Can the patient's head move within the helmet?
- Can the spine be immobilized in a neutral position with the helmet on?

A helmet that fits well prevents the patient's head from moving and should be left on, as long as (1) there are no impending airway or breathing problems, (2) it does not interfere with assessment and

treatment of airway or ventilation problems, and (3) you can properly immobilize the spine, which may involve padding underneath the shoulders. You should also leave the helmet on if there is any chance that removing it will further injure the patient.

Remove a helmet if (1) it is a full-face helmet, (2) it makes assessing or managing airway problems difficult and removal of a face guard to improve airway access is not possible, (3) it prevents you from properly immobilizing the spine, or (4) it allows excessive head movement.

Always remove a helmet from a patient who is in cardiac arrest.

Sports helmets are typically open in the front and may or may not include an attached face mask. The mask can be removed without affecting helmet position or function by simply removing or cutting the straps that hold it to the helmet. In this way, sports helmets allow easy access to the airway (**FIGURE 30-34**). Motorcycle helmets often have a

A

B

C

D

FIGURE 30-34 The mask on most sports helmets can be removed without affecting helmet position or function.

A. Stabilize the patient's head and helmet. Remove the face mask in one of two ways: Use a trainer's tool designed for cutting retaining clips (**B**), or unscrew the retaining clips for the face mask (**C**). **D.** After the face mask is removed, the helmet can be immobilized against the backboard and a bag-mask device can be used effectively.

shield covering the face. This, too, can be unbuckled to allow access to the airway. If a shield cannot be removed, the helmet must be removed.

Words of Wisdom

Sports helmets may require the use of a specific tool to remove the face mask. Coaches or staff will have the necessary tool and will be experienced in its use.

Words of Wisdom

If a football player's helmet is removed, the shoulder pads must also be removed or padding must be placed under the head to maintain the neck in a neutral, in-line position. Likewise, if a motorcycle or other helmet is not removed, padding must be applied underneath the shoulders to maintain spinal alignment.

Preferred Method

Removing a helmet is at least a two-person job; however, the technique for helmet removal depends on the actual type of helmet worn by the patient. One AEMT provides constant in-line support as the other moves; you and your partner should not move at the same time. You should first consult with medical direction, if possible, about your decision to remove a helmet. When you decide to do so, follow the steps in **SKILL DRILL 30-7**.

Remember, you do not need to remove a helmet if you can access the patient's airway, if the head is snug inside the helmet, and if the helmet can be secured to an immobilization device.

Words of Wisdom

Always take helmets to the hospital with the patient. Any damage evident on the helmet can alert physicians to areas of potential injury that may have been overlooked.

Skill Drill 30-7 Removing a Helmet

Step 1

Begin by kneeling at the patient's head. Your partner should kneel on one side of the patient, at the shoulder area. Open the face shield, if there is one, and assess the patient's airway and breathing. Remove eyeglasses if the patient is wearing them.

Step 2

Prevent head movement by placing your hands on either side of the helmet, with your fingers on the patient's lower jaw. After your hands are in position, your partner can loosen the face strap.

(continues)

Skill Drill 30-7 Removing a Helmet (*continued*)**Step 3**

After the strap has been loosened, your partner should place one hand on the patient's lower jaw at the angle of the lower jaw and the other behind the head at the occipital region. After your partner's hands are in position, you may pull the sides of the helmet away from the patient's head.

**Step 4**

Gently slip the helmet about halfway off the patient's head, stopping when the helmet reaches the halfway point.

**Step 5**

Your partner then slides their hand from the occiput to the back of the head. This will prevent the head from snapping back after the helmet has been completely removed.

**Step 6**

With your partner's hand in place, remove the helmet, taking care to work over the occiput and nose, and immobilize the cervical spine. Apply a cervical collar, and then secure the patient to a long backboard. With large helmets or small patients, you may need to pad under the shoulders to prevent flexion of the neck. If shoulder pads or heavy clothing are in place, you may need to pad behind the patient's head to prevent extension of the neck.

Alternate Method

An alternate method for removal of football helmets has also been used. The advantage of this method is that it allows the helmet to be removed with the application of less force, therefore reducing the possibility of motion occurring at the neck. The disadvantage of this method is that it is slightly more time consuming. The first step involves removal of the chin strap. This can be cut or unsnapped carefully. Be careful during removal of the chin strap to avoid jarring the neck or head and causing excessive motion. Next, remove the face mask. The face mask is anchored to the helmet by plastic clips secured with screws. These can be removed with a screwdriver or cut with a knife. After the face mask has been removed, the jaw pads can be popped out of place. This can be accomplished with the use of a tongue depressor (**FIGURE 30-35A**). You can then place your fingers inside the helmet, allowing greater control of the helmet during removal as the helmet is gently rocked back off the top of the head. The person at the side of the patient controls the head by holding the jaw with one hand and the occiput with the other (**FIGURE 30-35B**). Padding is inserted behind the occiput to prevent neck extension. If the shoulder pads are in place, appropriate padding must be applied behind the head to prevent hyperextension. As with the previously described method, the person at the patient's chest is responsible for making sure that the head and neck do not move during removal of the helmet.

Remember that small children may require additional padding to maintain the neutral, in-line position. Children are not small adults. They have smaller airways and proportionally larger heads, so padding is important to maintain the airway. Pad under the shoulders to the toes, as needed, to avoid excessive neck flexion (**FIGURE 30-36**). In addition, place blanket rolls between the child and the sides of an adult-size backboard to prevent the child from slipping to one side or the other (**FIGURE 30-37**). Appropriate-size backboards are available for children.

FIGURE 30-36 Children have proportionally larger heads than adults, so you may need to place padding under the shoulders to avoid excessive flexion of the neck.

Special Populations

You are likely to find infants and children who have been in motor vehicle crashes and are still in their car seats. Follow your local protocols regarding SMR techniques. See Chapter 36, *Pediatric Emergencies*, for a complete discussion on removing pediatric patients from car seats and performing SMR maneuvers.

Nontraumatic Spinal Conditions

Back pain is one of the most common physical ailments seen in EDs throughout the United States. Expenses related to back pain are high because of the extensive costs of therapy and lost wages from missed work days. Upright posture places a substantial amount of weight on the lumbar spine—specifically at L4-L5, where the natural bend in the spine's curvature changes. Therefore, most people are susceptible to injury or degenerative disease. Spinal tumors can also cause pain and debilitation. Most cases of low back pain are idiopathic (there is no known cause), making a precise diagnosis can be difficult.

When evaluating nontraumatic back pain, consider disease processes, including SCI, that can produce severely debilitating lesions (**TABLE 30-6**). In the absence of trauma, assess the patient's report of low back pain with the anatomy and neurophysiology of the spine and spinal cord in mind. Pay particular attention to the patient's medications; patients with chronic back pain and tumors may be taking high dosages of narcotic agents on their

own or on the advice of a physician to control their intense pain.

Pain may result from **strain** or **sprain** of paravertebral muscles and supporting ligamentous structures without substantial injury to nerve elements. Older adult patients (especially women) with a history of osteoporosis are at high risk for spontaneous compression fractures of the spine. These typically stable fractures are not associated with SCI. Tumors in the spine from a variety of metastatic carcinomas can cause pathologic spine fractures, with extension of bone fragments or the tumor itself into the spinal canal causing SCI.

Degenerative disk disease is a common entity. Over time, biomechanical and physiologic alterations of the intervertebral disk will result in loss of height and reduce the shock-absorbing effect of the disk. Substantial narrowing may result in variable segment stability.

Disk herniation may be caused by some degree of trauma in patients with preexisting disk degeneration. It typically affects men between ages 30 and 50 years, and may result from poor lifting technique. Herniation most commonly occurs at L4-L5 and L5-S1 but may also occur in C5-C6 and C6-C7. Patients will present with pain, usually with straining; they may have tenderness of the spine and often have limited range of motion. Patients may have alterations in sensation and motor functions as well. Cervical herniations may present with upper extremity pain or paresthesias that worsen with neck motion. Motor weakness may also occur as a result of spinal cord compression.

Definitive diagnosis of back pain may require multiple modalities of radiographic imaging. Prehospital management of low back pain in the absence of trauma is primarily palliative, directed at decreasing any pain or discomfort with movement.

Words of Wisdom

Some patients with acute low back spasm are literally paralyzed with pain. Scoop stretchers can be extremely helpful when moving these patients.

YOU are the Provider SUMMARY

1. On the basis of the information provided, what are some possible injuries you may encounter?

This patient may present with a multitude of injuries. Your primary concern should focus on life threats and SCIs, followed closely by TBIs. With the information provided by the lifeguards regarding the periods of unresponsiveness, you should suspect a serious TBI, which must be managed immediately to prevent worsening of the patient's condition.

2. Is this patient experiencing a primary or secondary brain injury?

This patient is most likely experiencing a primary brain injury—injury to the brain and its associated structures that results instantaneously from impact to the head. Conversely, secondary brain injury refers to injury from processes that may occur after the primary injury.

3. What would you expect this patient's vital signs to be?

Vital sign findings will vary tremendously from patient to patient. However, signs of mildly increased ICP include hypertension, bradycardia, and abnormal respirations. A patient with neurogenic shock will present with hypotension and normal to slow respirations and pulses. Skin will be dry and temperature will be based on the surrounding environment. If you suspect TBI, obtain multiple sets of vital signs to assist in recognizing an increase in ICP.

4. What are the signs and symptoms of a basilar skull fracture?

Signs of a basilar skull fracture include CSF drainage from the ears, which indicates rupture of the tympanic membrane and freely flowing CSF through the ear. Other signs of a basilar skull fracture include raccoon eyes or Battle sign. Depending on the extent of the damage, raccoon eyes and Battle sign may appear relatively quickly, but in many patients, they may not appear until up to 24 hours following the injury, so their absence in the field does not rule out a basilar skull fracture.

5. On the basis of your examination findings, what degree of elevated ICP does he have?

This patient is presenting with mildly elevated ICP. Mild elevation is characterized by an increase in blood pressure, decreased pulse rate, and abnormal respirations. The key finding in mild elevation is reactive pupils. Once you can recognize pupillary changes, the increased pressure has moved out of the mild category and into the moderate or severe category.

6. If this patient was unable to maintain his airway, at what rate would you initially ventilate using a bag-mask device?

Patients with cerebral edema should be ventilated at a rate of 10 breaths/min or as determined by local protocols. Hyperventilating a patient may cause vasoconstriction, further reducing oxygenation of the brain. However, if the patient exhibits late signs of increased ICP (the Cushing triad, unequal or nonreactive pupils, coma, or posturing), ventilate at a slightly increased rate (20 breaths per minute for adults). Follow local protocols and your medical direction regarding hyperventilation in the presence of evidence of herniation.

7. At what point should you start hyperventilating the patient with a head injury?

Start hyperventilating the patient when he presents with signs of cerebral herniation. This includes unresponsiveness, the Cushing triad, unequal or nonreactive pupils, and/or posturing.

8. What is the appropriate hospital for this patient?

Many patients with severe brain injuries and increased ICP require neurosurgical intervention. The extra time it takes to move the patient from one hospital to another could mean the difference between life and death. Therefore, consider transporting the patient directly to a trauma center that has neurosurgical capabilities if it will decrease the time to surgical intervention, even if it means bypassing the nearest hospital, always taking into consideration your local protocols.

Narrative

EMS dispatched to the YMCA pool for possible spinal injury. On arrival, patient found alongside of pool with lifeguards in attendance. Senior lifeguard states that patient was running alongside the pool when he slipped and fell into the pool headfirst, striking his head on the bottom. Lifeguards immediately placed the patient onto floating backboard and extricated him from the pool. They state he has been "in and out" of responsiveness since the incident. Patient found AO x 4, ABCs intact. Patient states that he cannot feel his arms or legs. Manual stabilization established. Physical examination reveals approximately 2-inch hematoma on posterior scalp, also noted to have no motor or sensation to bilateral arms or legs, but pulses are present. Placed patient on 15 L/min via nonrebreathing mask, cervical collar applied, and patient secured to backboard. Initial vitals as above, noted to have signs and symptoms indicative of increased ICP. GCS calculated to be 10 (alert [4], oriented [5], no motor function [1]). 18-gauge IV established to right forearm with NS TKO. Emergent transport initiated to St. Luke's trauma center ED. Approximately 6 minutes into transport, patient became unresponsive with episodes of apnea. Inserted OPA and began initial ventilations at 10 breaths/min. GCS recalculated to be 3 (unresponsive [1], no verbal [1] or motor [1] function). Report called to ED with condition and ETA. ED reports they do not have neurosurgeon today and to divert to Mercy Hospital trauma center. Divert acknowledged, with report given to Mercy trauma center ED. On arrival, care and report given to staff without incident.

End of report

Prep Kit

Ready for Review

- Important anatomic structures in the head and spine include the scalp; the skull, which includes the cranium and the face; the spinal column and its vertebrae; the brain; and the meninges.
- The brainstem houses many structures that are critical to the maintenance of vital functions, such as heart rate, blood pressure, and respiration. Damage to this area can easily result in cardiovascular derangement, respiratory arrest, or death.
- The nervous system is divided into two parts: the CNS and the PNS.
- The CNS consists of the brain and the spinal cord. The cables of nerve fibers linking nerve cells in the brain and spinal cord to the body's organs make up the PNS.
- The part of the nervous system that regulates our voluntary activities is called the somatic or voluntary nervous system.
- The much more primitive autonomic or involuntary nervous system regulates involuntary body functions. The autonomic nervous system is composed of the sympathetic and parasympathetic nervous systems, which balance each other.
- Common head trauma includes skull wounds (scalp lacerations and skull fracture) and brain injuries (concussion, contusion, intracranial bleeding), typically caused by direct blows, motor vehicle crashes, falls from heights, assault, and sports injuries.
- Signs and symptoms of head trauma include lacerations, visible deformities of the skull, ecchymosis around the eyes or behind the ear, unequal pupil size and failure of the pupils to respond to light, loss of sensation and/or motor function, visual disturbances, irregular respirations, and posturing, among others.
- Types of skull fractures include linear, depressed, basilar, and open.
- TBIs can produce physical, intellectual, emotional, social, and vocational changes. They may be classified as primary or secondary.
- Cerebral edema, seizures, vomiting, and leakage of cerebrospinal fluid are common complications of open and closed head injuries.
- Bleeding inside the skull increases ICP, the pressure within the cranial vault. In the field, the severity of increased ICP can be estimated based on the patient's clinical presentation. Prehospital treatment must focus on maintaining CPP while mitigating increased ICP as much as possible.
- If increased ICP is not promptly treated in a definitive care setting, cerebral herniation may occur, in which the brain is forced from the cranial vault. Cerebral herniation is a fatal event.
- Early signs and symptoms of increased ICP include vomiting, headache, altered level of consciousness, and seizures. Later ominous signs include the Cushing triad plus a unilaterally unequal and nonreactive pupil, coma, and decorticate or decerebrate posturing.
- Bleeding in the brain can take the form of an epidural hematoma, subdural hematoma, intracerebral hematoma, or subarachnoid hemorrhage, depending on where the bleeding is occurring.
- A blow to the head or face may cause a concussion of the brain. A concussion injury results in cerebral dysfunction that usually resolves spontaneously and rapidly without demonstrable physical damage to the brain.

or permanent neurologic impairment. Signs of a concussion include confusion and disorientation. If there is any suspicion of concussion, the patient must desist from sports activity and be assessed by a physician prior to return to play.

- Diffuse axonal injury is a severe concussive injury to the brain resulting in physical damage to nerve fibers.
- A cerebral contusion is a bruise of brain tissue. As with any bruise, swelling will occur, which results in increased ICP.
- Spinal injuries are categorized as primary SCI and secondary SCI. Mechanisms include flexion, rotation with flexion, vertical compression, distraction, and hyperextension. Distracting injury (different than distraction) is an important concept; an injury that causes substantial pain may render the patient unable to notice signs or symptoms of spinal column injury.
- Patients with head injuries often have injuries to the cervical spine as well. Therefore, when treating a patient with a head injury, you must protect and stabilize the cervical spine at all times.
- Patient assessment begins with an awareness of high-risk mechanisms that strongly suggest spine injury. If you suspect a spinal injury, keep the head in a neutral, in-line position throughout your assessment and treatment, and follow local protocols regarding further SMR procedures.
- As always, focus on addressing airway, breathing, and circulation; it is also important to prevent aspiration.
- Closely monitor the patient's oxygen saturation level and maintain it at 95% or higher. Cerebral edema and ICP are aggravated by hypoxia and hypercapnia. Ventilate an adult with a brain injury at a rate of 10 breaths/min or as determined by local protocols.
- A single episode of hypoperfusion in a patient with a head injury can result in substantial brain damage and even death. Assess for signs and symptoms of shock and treat appropriately. Volume resuscitation may be necessary.
- Perform baseline and frequent reassessments of the patient's level of consciousness using the GCS or another such tool and document all values. These measurements are important to determine the patient's clinical progression.
- Prompt transport to a definitive care facility (ie, a trauma center) is crucial to the survival of a patient with a brain injury.
- Cervical collars provide preliminary, partial immobilization of the spine. A patient who is supine can be further stabilized with a long backboard. Alternative methods include use of a scoop stretcher or a vacuum mattress.
- With sitting patients, you should use a short immobilization device, then secure the short device to a long board.
- A helmet that fits well prevents the patient's head from moving and should be left on, as long as it does not interfere with assessment and treatment of airway or ventilation problems and you can properly immobilize the spine. Remove a helmet if it makes assessing or managing airway problems difficult, prevents you from immobilizing the spine, or allows excessive head movement.
- Never remove a helmet if doing so will further injure the patient. Always remove a helmet if the patient is in cardiac arrest.
- Back pain is a common presenting ailment. Obtain the patient's history and perform a physical exam. Any patient with a suspected nontraumatic spinal disorder should undergo a neurologic evaluation.

Vital Vocabulary

anterograde (posttraumatic) amnesia Inability to remember events after an injury.

arachnoid The middle membrane of the three meninges that enclose the brain and spinal cord.

autonomic nervous system The part of the nervous system that regulates functions that are not controlled consciously, but rather involuntarily, such as heart rate, blood pressure, digestion, and sweating.

autoregulation An increase in mean arterial pressure to compensate for decreased cerebral perfusion pressure; a compensatory physiologic response that occurs in an effort to shunt blood to the brain; manifests clinically as hypertension.

axon A long, slender extension of a neuron (nerve cell) that conducts electrical impulses away from the neuronal soma.

basal ganglia Structures located deep within the cerebrum, diencephalon, and midbrain that have an important role in coordination of motor movements and posture.

basilar skull fracture An injury that usually occurs following diffuse impact to the head (such as falls and motor vehicle crashes); generally results from extension of a linear fracture to the base of the skull and can be difficult to diagnose without CT scan.

Battle sign Bruising behind an ear over the mastoid process that may indicate a skull fracture.

Biot respirations Characterized by an irregular rate, pattern, and volume of breathing with intermittent periods of apnea; also called ataxic respirations.

brainstem The area of the brain between the spinal cord and cerebrum, surrounded by the cerebellum; controls functions that are necessary for life, such as respiration and cardiac system functions.

cauda equina The collection of nerves at the end of the spinal cord; consists of the second through

fifth lumbar nerve pairs, the first through fifth sacral nerve pairs, and the coccygeal nerve.

central nervous system (CNS) The brain and spinal cord.

central neurogenic hyperventilation Deep, rapid respirations; similar to Kussmaul, but without an acetone breath odor; commonly seen following brainstem injury.

cerebellum One of the three major subdivisions of the brain, sometimes called the athlete's brain; coordinates the various activities of the brain, particularly fine body movements.

cerebral contusion A focal brain injury in which brain tissue is bruised and damaged in a defined area.

cerebral cortex The largest portion of the cerebrum; regulates voluntary skeletal movement and a person's level of awareness—a part of consciousness.

cerebral edema Swelling of the brain.

cerebral perfusion pressure (CPP) The pressure of blood flow through the brain; the difference between the mean arterial pressure (MAP) and intracranial pressure (ICP).

cerebrospinal fluid (CSF) Fluid produced in the ventricles of the brain that flows in the subarachnoid space and bathes the meninges.

cerebrum The largest part of the three subdivisions of the brain, sometimes called the gray matter; made up of several lobes that control movement, hearing, balance, speech, visual perception, emotions, and personality.

Cheyne-Stokes respirations The respirations that are fast and then become slow, with intervening periods of apnea; commonly seen following brainstem injury.

closed head injury An injury in which the brain has been injured but the skin has not been broken and there is no bleeding.

concussion A temporary loss or alteration of part or all of the brain's abilities to function without actual physical damage to the brain.

connecting nerves The nerves in the brain and spinal cord that connect the motor and sensory nerves.

coup-contrecoup injury Dual impacting of the brain into the skull; coup injury occurs at the point of impact; contrecoup injury occurs on the opposite side of impact, as the brain rebounds.

Cushing triad Hypertension (with a widening pulse pressure), bradycardia, and irregular respirations; classic trio of findings associated with increased intracranial pressure.

decerebrate (extensor) posturing A posture characterized by extension of the arms and legs, in which the arms rotate in a palms-down manner and the toes point; indicates pressure on the brainstem and may appear in patients with severe brain trauma.

decorticate (flexor) posturing A posture characterized by flexion of the arms and extension of the legs, in which the arms flex and curl toward the chest, the wrists flex, and the toes point; indicates pressure on the brainstem and may appear in patients with severe brain trauma.

depressed skull fracture A type of skull fracture that results from high-energy direct trauma to a small surface area of the head with a blunt object (such as a baseball bat to the head); commonly results in bony fragments being driven into the brain, causing injury.

diffuse axonal injury (DAI) Diffuse brain injury that is caused by stretching, shearing, or tearing of nerve fibers with subsequent axonal damage.

diffuse brain injury Any injury that affects the entire brain.

distraction The action of pulling the spine along its length.

dura mater The outermost layer of the three meninges that enclose the brain and spinal cord; the toughest meningeal layer.

epidural hematoma An accumulation of blood between the skull and the dura mater.

flexion injuries A type of injury that results from forward movement of the upper body, typically as the result of rapid deceleration, such as in a motor vehicle crash, or with a direct blow to the occiput.

flexion-rotation injuries A type of injury in which both rotation and flexion occur; typically resulting from high acceleration forces; can result in a stable unilateral facet dislocation in the cervical spine.

focal brain injury A specific, grossly observable brain injury.

four-person log roll The recommended procedure for moving a patient with a suspected spinal injury from the ground to a long backboard.

frontal lobe The portion of the brain that is important in voluntary motor actions and personality traits.

Glasgow Coma Scale (GCS) A method of evaluating the level of consciousness that uses a scoring system for neurologic responses to specific stimuli.

hangman's fracture The most classic distraction injury, which occurs when a person is hanged by the neck. The result is a bilateral fracture of C2 with an associated traumatic subluxation of C2 on C3.

head injury A traumatic insult to the head that may result in injury to soft tissue of the scalp and bony structures of the head and skull, not including the face.

head trauma A general term that includes both head injuries and traumatic brain injuries.

herniation A process in which tissue is forced out of its normal position, such as when the brain is forced from the cranial vault, either through the foramen magnum or over the tentorium.

hyperextension Extension beyond the usual range of motion.

hyperpyrexia A high body temperature.

intervertebral disks The cushions that lie between the vertebrae.

intracerebral hematoma Bleeding within the brain tissue (parenchyma) itself; also referred to as an intraparenchymal hematoma.

intracranial pressure (ICP) The pressure within the cranial vault.

involuntary activities Actions of the body that are not under a person's conscious control.

linear skull fractures Types of skull fracture that commonly occur in the temporal-parietal region of the skull; not associated with deformities to the skull; also referred to as nondisplaced skull fractures.

mean arterial pressure (MAP) The average pressure against the arterial wall during a cardiac cycle; generally considered to be the same as blood pressure.

medulla A part of the brainstem that continues inferiorly with the spinal cord; serves as a conduction pathway for ascending and descending nerve tracts; coordinates heart rate, blood vessel diameter, breathing, swallowing, vomiting, coughing, and sneezing.

meninges A set of three tough membranes, the dura mater, arachnoid, and pia mater, that enclose and protect the entire brain and spinal cord within the skull and the spinal canal.

motor nerves Nerves that carry information from the central nervous system to the muscles of the body.

nerve root injury Injury to a nerve at the level of the spinal cord.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, resulting in widespread vasodilation and loss of sympathetic nervous system tone; seen in patients with spinal cord injuries.

neuronal soma The body of a neuron (nerve cell).

occipital lobe The portion of the brain that is responsible for the processing of visual information.

open head injury An injury to the head often caused by a penetrating object in which there may be bleeding and exposed brain tissue.

parasympathetic nervous system A subdivision of the autonomic nervous system, involved in control of involuntary, vegetative functions, mediated largely by the vagus nerve through the chemical acetylcholine; the part of the autonomic nervous system that relaxes the body.

parietal lobe The portion of the brain that is the site for reception and evaluation of most sensory information, except smell, hearing, and vision.

peripheral nerve injury Injury to a nerve anywhere in the body outside the spinal cord.

peripheral nervous system (PNS) The 31 pairs of spinal nerves and 12 pairs of cranial nerves that link the body's other organs to the central nervous system; these may be sensory, motor, or connecting nerves.

petechial hemorrhages Pinpoint red dots in the sclera of the eye.

pia mater The innermost and thinnest of the three meninges that enclose the brain and spinal cord; it rests directly on the brain and spinal cord.

pons An organ that lies below the midbrain and above the medulla and contains numerous important nerve fibers, including those for sleep, respiration, and the medullary respiratory center.

primary brain injury A sudden and profound injury to the brain that is essentially complete at the time of impact; may be caused, for example, by an explosive pressure wave on the hollow organs of the body.

primary spinal cord injury Injury to the spinal cord that is a direct result of trauma, for example transection of the spinal cord from penetrating trauma or displacement of ligaments and bone fragments, resulting in compression of the spinal cord.

raccoon eyes Bruising under the eyes that may indicate a skull fracture; also called periorbital ecchymosis.

reticular activating system (RAS) A structure located in the upper brainstem; responsible for maintenance of consciousness, specifically a person's level of arousal.

retrograde amnesia The inability to remember events leading up to a head injury.

secondary brain injury The “aftereffects” of the primary injury; includes injuries caused by abnormal processes such as cerebral edema, increased intracranial pressure, cerebral ischemia and hypoxia, and infection; onset is often delayed following the primary brain injury.

secondary spinal cord injury Injury to the spinal cord, thought to be the result of multiple factors that result in a progression of inflammatory responses from primary spinal cord injury.

sensory nerves The nerves that transmit sensory input, such as touch, taste, heat, cold, and pain, from the body to the central nervous system.

somatic nervous system The part of the nervous system that regulates a person's voluntary activities, such as walking, talking, and writing.

spinal cord concussion An incomplete injury of the spinal cord in which temporary dysfunction lasts from 24 to 48 hours; may present in patients with simple compression fractures.

spinal cord contusion A bruise of the spinal cord characterized by edema, tissue damage, and vascular leakage, and caused by fracture, dislocation, or direct trauma.

spinal shock The temporary local neurologic condition that occurs immediately after spinal trauma; swelling and edema of the spinal cord begin immediately after injury, with severe pain and potential paralysis.

sprain A joint injury involving damage to supporting ligaments (stretching or tearing) and partial or temporary dislocation of bone ends.

strain Stretching or tearing of a muscle or tendon; also called a muscle pull.

subarachnoid hemorrhage A hemorrhage into the subarachnoid space between the arachnoid membrane and the pia mater, where the cerebrospinal fluid circulates.

subdural hematoma An accumulation of blood beneath the dura mater but outside the brain.

subluxation A partial or incomplete dislocation of a joint.

sympathetic nervous system The subdivision of the autonomic nervous system that governs the body's fight-or-flight reactions by inducing smooth muscle contraction or relaxation of the blood vessels and bronchioles; responsible for the body's response to shock and stress.

temporal lobe The portion of the brain that has an important role in hearing and memory.

tentorium A structure that separates the cerebral hemispheres from the cerebellum and brainstem.

traumatic brain injury (TBI) A traumatic insult to the brain capable of producing physical, intellectual, emotional, social, and vocational changes.

vertebral body Anterior weight-bearing structure in the spine made of cancellous bone and surrounded by a layer of hard, compact bone that provides support and stability.

vertical compression A type of injury typically resulting from a direct blow to the crown of the skull or rapid deceleration from a fall through the feet, legs, and pelvis, possibly causing a burst fracture or disk herniation.

voluntary activities The actions that we consciously perform, in which sensory input determines the specific muscular activity.

Chapter 31

Chest Injuries

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Chest Trauma

Recognition and management of

- Blunt versus penetrating mechanisms (pp 1468–1470)
- Open chest wound (pp 1468–1471)
- Impaled object (pp 1468–1471)

Pathophysiology, assessment, and management of

- Blunt versus penetrating mechanisms (pp 1468–1477)

- Hemothorax (pp 1486–1487)
- Pneumothorax (pp 1481–1486)
 - Open (pp 1483–1484)
 - Simple (pp 1481–1483)
 - Tension (pp 1484–1486)
- Cardiac tamponade (pp 1488–1490)
- Rib fractures (pp 1478–1479)
- Flail chest (pp 1479–1480)
- Commotio cordis (p 1481)
- Traumatic aortic disruption (pp 1490–1491)
- Pulmonary contusion (pp 1487–1488)
- Blunt cardiac injury (p 1490)
- Traumatic asphyxia (p 1493)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the thorax. (pp 1464–1468)
2. Understand the mechanics of ventilation in relation to chest injuries. (pp 1466–1468)
3. Discuss specific chest injuries, including closed versus open chest injury; blunt versus penetrating trauma; and effects on cardiac output, respiration, and ventilation. (pp 1466–1468)
4. Differentiate between a pneumothorax (open, simple, and tension) and a hemothorax. (pp 1481–1487)
5. List general signs and symptoms of a chest injury. (pp 1470–1471)
6. Discuss the significance of various signs and symptoms of chest injury, including changes in heart rate, dyspnea, jugular venous distention, muffled heart sounds, changes in blood pressure, diaphoresis or changes in pallor, hemoptysis, and changes in mental status. (pp 1470–1471)
7. Explain the assessment process for a patient with a chest injury. (pp 1471–1477)
8. Explain the general management of a patient with a chest injury. (p 1477)
9. Explain the assessment and management of chest wall injuries, including rib fractures, flail chest, sternal fracture, clavicle fracture, and commotio cordis. (pp 1478–1481)
10. Describe the complications of rib fractures. (pp 1478–1479)

11. Describe the complications of flail chest. (pp 1479–1480)
12. Explain the assessment and management of lung injuries, including simple pneumothorax, open pneumothorax, tension pneumothorax, hemothorax, and pulmonary contusion. (pp 1481–1488)
13. Explain the complications associated with an open pneumothorax (sucking chest wound). (pp 1483–1484)
14. Explain the assessment and management of myocardial injuries, including cardiac tamponade, myocardial contusion, and myocardial rupture. (pp 1488–1490)
15. Describe the complications of cardiac tamponade. (pp 1488–1490)
16. Explain the assessment and management of vascular injuries, including traumatic aortic disruption and penetrating wounds of the great vessels. (pp 1490–1492)
17. Explain the assessment and management of other thoracic injuries, including diaphragmatic injury, esophageal injury, tracheobronchial injury, and traumatic asphyxia. (pp 1492–1493)

SKILLS OBJECTIVES

1. Describe the steps to take in the assessment of a patient with a suspected chest injury. (pp 1471–1477)
2. Demonstrate the management of a patient with a sucking chest wound. (pp 1483–1484)
3. Demonstrate the management of a patient with a flail chest. (pp 1479–1480)

Introduction

Thoracic injuries are common and, given the likelihood of damage to the heart, lungs, or great blood vessels, potentially very serious. Any injury that interferes with normal breathing must be treated without delay to prevent permanent damage to tissues that depend on a continuous supply of oxygen. Another major problem with chest injuries may be internal bleeding. Blood from lacerations of the thoracic organs or major blood vessels can collect in the chest cavity, compressing the lungs. Also, air can collect in the chest and prevent the lungs from expanding. As an advanced emergency medical technician (AEMT), your ability to act quickly to care for patients with these injuries can make the difference between survival and death. Prevention strategies include gun safety education, sports training, use of seat belts, and other protective measures.

Currently, thoracic trauma accounts for a substantial number of serious injuries and fatalities each year. On average, 214,000 people die each year in the United States from injuries and violence.¹ Thoracic trauma is a leading cause of death among trauma victims, second only to traumatic brain injury. An estimated one in four trauma deaths is directly the result of thoracic injuries, and thoracic trauma is a contributing factor in another 25% of trauma patients who die of their injuries.²

The mechanism producing these injuries often involves a great deal of force transmitted to the body, with motor vehicle crashes (MVCs) accounting for most patients with blunt thoracic trauma.³

This chapter begins with a review of the anatomy of the chest and the physiology of respiration. It then describes the common signs and symptoms of thoracic injuries and the proper emergency medical treatment for specific injuries.

Anatomy and Physiology Review

Anatomy Review

To understand and evaluate chest injuries in the prehospital setting, you must first understand the anatomy of the chest and the mechanism by which gases are exchanged during breathing. A quick review will help you to appreciate the logic in the emergency treatment of chest injuries and the potential complications of that treatment.

The thoracic cavity extends from the lower end of the neck to the diaphragm (**FIGURE 31-1**). In a person who is lying down or who has just completed exhalation, the diaphragm may rise as high as the nipple line. Thus, a penetrating injury to the chest, such as a gunshot or stab wound, may also penetrate the lung and diaphragm and injure the liver or stomach. For this reason, any chest injury at or

FIGURE 31-1 A view of the anterior aspect of the thoracic cage shows the major organs beneath the surface.

© Jones & Bartlett Learning.

below the nipple line should be considered both a thoracic injury and an abdominal injury.

The central region of the thorax is the **mediastinum**, which contains the heart, great vessels, esophagus, lymphatic channels, trachea, main stem bronchi, and paired vagus and phrenic nerves. It encompasses all structures located in the center of the chest, excluding the lungs. The contents of the thorax are partially protected by the ribs, which are connected in the back to the 12 thoracic vertebrae and in the front, through the costal cartilages, to the sternum (**FIGURE 31-2**). The muscles of the thorax help protect the underlying organs and provide the necessary movement for breathing.

The intercostal muscles (located between the ribs) and the diaphragm are the primary muscles of respiration. The sternocleidomastoid muscles

FIGURE 31-2 The organs within the thoracic cage are protected by the ribs, which are connected in back to the vertebrae and in the front, via the costal cartilages, to the sternum.

YOU are the Provider

Part 1

While providing standby services to a local motocross track, you and your partner are summoned to the course for a man who landed improperly after making a large jump, crashing his dirt bike. As you and your partner are preparing to enter the track, you note another dirt bike rider coming down from the jump, impacting your patient's chest with the front tire of his bike.

1. Should you immediately approach the patient? Is the scene safe?
2. What are some possible injuries this patient could have?

that provide support and movement in the neck are accessory muscles of respiration. The trapezius, rhomboids, and latissimus dorsi muscles provide the covering for the framework of the posterior thorax, and the pectoralis major surrounds the rib cage in the front.

The trachea, which is in the middle of the neck, divides at the carina (the last tracheal cartilage) into the left and right main stem bronchi, which supply air to the lungs. The bronchi divide into the smaller bronchioles and, finally, terminate in the alveoli. The pulmonary capillaries surround the alveoli, creating an interface for gas exchange. The lungs occupy the entire thoracic cavity except the mediastinum.

The esophagus enters the thorax via the thoracic inlet and travels through the posterior of the chest, exiting through the esophageal foramen through the diaphragm. It connects the pharynx superiorly with the stomach and the abdomen. The diaphragm forms the inferior border of the thoracic cavity and the superior border of the abdominal cavity.

Words of Wisdom

Consider any chest injury below the nipple line to be an abdominal injury as well as a thoracic injury.

The nerves supplying the diaphragm (the phrenic nerves) exit the spinal cord at C3, C4, and C5. A patient whose spinal cord is injured at the C5 level or below may lose the ability to move the intercostal muscles, but the diaphragm will still contract. The patient will still be able to breathe because the phrenic nerves remain intact. Patients with spinal cord injuries at C3 or above can completely lose their ability to breathe spontaneously (**FIGURE 31-3**).

Physiology Review

Ventilation occurs through expansion and contraction of the thoracic cage. Through a bellows system, the intercostal muscles between the ribs contract, elevating the rib cage and pulling the sternum forward on inhalation. At the same time, the diaphragm contracts and descends, pushing the contents of the abdomen down. The pressure inside the chest decreases, and air enters the lungs through the nose and mouth. Inspiration is an active

FIGURE 31-3 A patient who sustains a spinal cord injury at the level of C5 or below is paralyzed but can still breathe because the phrenic nerve, which controls the diaphragm, originates at the C3, C4, and C5 levels.

© Jones & Bartlett Learning.

process, whereas expiration is a passive process. On exhalation, the intercostal muscles and diaphragm relax, and the tissues move back to their normal positions. Air enters and leaves the lungs because of the changes in the intrathoracic pressure.

While *pulmonary respiration* is occurring, blood is being delivered via pulmonary circulation to the capillaries that lie adjacent to the alveoli. This blood has returned to the heart after traversing the body, delivering oxygen (O_2) to the cells, and removing cellular waste products such as carbon dioxide (CO_2). As a result, the blood entering the capillaries adjacent to the alveoli has a low O_2 concentration and a high CO_2 concentration.

The process of oxygenation includes the delivery of O_2 from the air to the blood, where it is carried to cells and tissues throughout the body. Because the air entering the alveoli contains a higher

concentration of O₂ (ranging from 21% in room air to as much as 100% in a nonrebreathing mask or bag-mask device under ideal circumstances) than the blood in the nearby capillaries, the O₂ will follow its concentration gradient and enter the blood. Most of the O₂ binds to hemoglobin within the red blood cells, and the O₂ returns to the heart with the blood, where it is then pumped throughout the body.

The ability to pump blood depends on having a functional pump (the heart), an adequate volume of blood to be pumped, and a lack of resistance to the pumping mechanism (afterload)—properties that collectively determine the cardiac output. **Cardiac output** is defined as the volume of blood delivered to the body in 1 minute. It equals the heart rate (beats/min) multiplied by the stroke volume (milliliters of blood per beat). Any injury that limits the heart's pumping ability, the delivery of blood to the heart, the blood's ability to leave the heart, or the heart rate will affect cardiac output.

Ventilation is the exchange of air between the lungs and the environment. The air in the environment typically contains low levels of CO₂ (0.033%). As a result, when air enters the alveoli, it contains little CO₂ compared with the blood in the nearby capillaries. The CO₂ diffuses down its concentration gradient, leaving the blood and entering the air within the alveoli.

As the diaphragm and the chest wall relax, positive pressure is created within the thorax. The air from which O₂ has been absorbed and into which CO₂ has been diffused is then exhaled. With each subsequent respiration (inhalation and exhalation), the process is repeated.

Even though the respiratory centers in the pons and medulla have a major role in regulating breathing, chemical changes are among the most important factors that influence the rate and depth of breathing. These chemical factors include changing levels of CO₂, O₂, and hydrogen ions in arterial blood. In respiratory physiology, **chemoreceptors** are sensors that respond to such chemical fluctuations and have two major body locations. Central chemoreceptors are found in the medulla, and peripheral chemoreceptors are located in the carotid and aortic bodies. Chemoreceptors closely monitor changes in CO₂ levels and stimulate breathing accordingly.

Increasing levels of CO₂ are mediated mainly through influence on the central chemoreceptors

of the brainstem. Carbon dioxide diffuses from the blood into the cerebrospinal fluid, where it is hydrated and forms carbonic acid. It then dissociates, freeing hydrogen and decreasing the pH of the cerebrospinal fluid. This excites the central chemoreceptors to increase the rate and depth of respirations.

(Increased levels of CO₂ combine with water to make carbonic acid. Carbonic acid is weak and easily dissociates, liberating hydrogen ions and decreasing the pH of the cerebrospinal fluid.)

Even though the increase in levels of CO₂ is the initial stimulus, it is the rising hydrogen ion levels that incite the central chemoreceptors into action in an attempt to maintain homeostasis by regulating hydrogen ion concentrations in the brain.

Respiratory alkalosis is the result of hyperventilation, regardless of the cause. As CO₂ levels decrease, there is a reduction in circulating carbonic acid. Treatment for the classic hyperventilation syndrome focuses on restoring the normal respiratory rate to increase levels of carbon dioxide. If the hyperventilation is caused by a serious medical condition, then reducing the respiratory rate may seriously aggravate the problem (**FIGURE 31-4**).

Respiratory acidosis is always related to the body's inability to remove CO₂, and chest trauma is a common cause of respiratory acidosis. A buildup of CO₂ and the respiratory system's inability to excrete it cause the body to rely on the much slower renal system for compensation. The acidosis that results is quick, overwhelming, and usually fatal, making it impossible for the slower-acting renal system to compensate in time for the pH shift (**FIGURE 31-5**).

Changes in arterial pH can modify the respiratory rate and depth even when CO₂ and O₂ levels are normal. This occurs in metabolic imbalances. Because few hydrogen ions diffuse from the blood into the cerebrospinal fluid, there is little effect on central chemoreceptors. Ventilation changes occur in response to changes in pH detected by the peripheral chemoreceptors. A decrease in blood pH may be the result of CO₂ retention or a metabolic cause such as an increase in lactic acid. As the arterial

A

B

FIGURE 31-4 A. Derangement of acid-base balance in respiratory alkalosis. **B.** Compensation by excretion of bicarbonate.

© Jones & Bartlett Learning.

pH falls, the respiratory system compensates by increasing the rate and depth of respirations in an attempt to eliminate CO_2 and, in turn, increase the pH level. The reverse occurs in metabolic alkalosis, in which the respiratory rate and depth decrease in an attempt to retain CO_2 and lower pH levels.

Pathophysiology

Mechanisms of injury (MOIs) in thoracic trauma can be separated into two general categories: blunt and penetrating. A thorough scene size-up will help you determine the forces involved.

Chest injuries can also be sorted into the categories of open and closed. As the name implies, a

A

B

FIGURE 31-5 A. Derangement of acid-base balance in respiratory acidosis. **B.** Compensation by formation of bicarbonate.

© Jones & Bartlett Learning.

closed chest injury is one in which the skin overlying the injury remains intact. This type of injury is generally caused by blunt trauma, such as when a driver strikes a steering wheel in a MVC or is struck by a falling object (**FIGURE 31-6**). The force is distributed over a large area. Visceral injuries occur from deceleration, shearing forces, compression, or rupture. In an **open chest injury**, the chest wall itself is penetrated by some object, such as a knife, a bullet, or a piece of metal (**FIGURE 31-7**). Penetrating injuries often distribute the forces of injury over a smaller area; however, the trajectory of a bullet is often unpredictable and all thoracic structures are at risk.

In blunt trauma, a blow to the chest may fracture the ribs, the sternum, or whole areas of the

chest wall; bruise the lungs and the heart; and even damage the aorta. In fact, traumatic rupture of the aorta is the second most common cause of death in MVCs, after head injury.⁴ Although the skin and

FIGURE 31-6 Closed injuries usually result from blunt trauma, such as when a patient strikes the steering wheel or an airbag in a motor vehicle crash or is struck by a falling object. A closed chest injury can even occur when a seat belt is worn.

Courtesy of Rhonda Hunt.

chest wall are not penetrated in a closed injury, broken ribs may lacerate the intrathoracic organs. Indeed, vital organs can be torn from their attachment in the chest cavity without any break in the skin.

Blast injuries may be classified as blunt or penetrating. The shock wave during the primary blast compresses organs similar to blunt trauma. During the secondary phase of blast injury, objects may be thrown and penetrate the body.

Thoracic trauma may impair cardiac output, decreasing blood pressure and perfusion to vital organs. Considering the contents of the thoracic cavity, any injury to the chest has the potential to be lethal. Trauma may result in blood loss, pressure changes, vital organ damage, or any combination of

FIGURE 31-7 Open injuries occur when the chest wall is penetrated by some type of object.

YOU are the Provider

Part 2

As you enter the track, you note that both patients are wearing personal protective equipment, including a helmet, knee and elbow pads, and a chest protector. When you reach the patients, you quickly manually stabilize the cervical spine and triage the original patient, while your partner triages the other patient. Your patient is alert, oriented, and able to recall all events. However, he has severe dyspnea and pain on palpation to the midchest area.

Recording Time: 1 Minute

Appearance	Anxious
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Appears patent
Breathing	Shallow and rapid; increased work of breathing
Circulation	Strong radial pulse; skin warm and dry

- Does this patient require spinal immobilization?
- Does this patient require helmet removal?

these. Bleeding into the thoracic cavity significantly increases the chance of hypovolemia and hypoxia. Increased intrapleural pressures not only decrease lung volume and oxygenation but also impair the heart's ability to pump effectively. Blood in the pericardial sac compresses the heart, eventually stopping it altogether. Myocardial valve damage from trauma to the heart can disrupt ventricular filling, allowing for backflow into the atria and further decreasing cardiac output. Vascular disruption may also occur as the result of trauma. A rupture of a major vessel can lead to fatal blood loss, and even a small tear or blockage can cause lack of oxygenation and tissue ischemia. You should have a good understanding of the underlying structures of the chest because this knowledge improves your assessment abilities and may increase the patient's chance of survival.

Aside from massive blood loss, impairments in ventilatory efficiency may also be rapidly fatal. Any injury that compromises the chest bellows action decreases air exchange and subsequent oxygenation. A patient experiencing severe chest pain tends to breathe shallowly in an attempt to decrease the discomfort created by movement. This further reduces **minute volume**, the volume of air exchanged between the lungs and environment in 1 minute. Air may enter the **pleural space**, which is potential space between the visceral and parietal pleura of the lung and chest wall, respectively. This space is normally absent, as these two pleural surfaces are in direct contact in the normal, uninjured chest. In cases of pneumothorax, however, the pleural space is created and air can be introduced between the two pleural surfaces. In **hemothorax**, blood accumulates between them.

Air entering the pleural space as the result of an open or closed pneumothorax, a tracheal tear, or other damage compresses the lungs and decreases tidal volume. This problem also occurs when blood collects in the thoracic cavity and prevents full expansion of the lungs. Various injuries caused by chest trauma, such as rib fractures and diaphragmatic injury, result in fewer pressure changes and, therefore, less movement of air, which further decreases the amount of oxygen available for gas exchange.

Other complications are also capable of impairing gas exchange. **Atelectasis** is alveolar collapse that prevents the use of that portion of the lung

for ventilation and oxygenation. Atelectasis significantly reduces the surface area available for gas exchange. The more alveoli that are damaged, the less gas exchange occurs. Bruised lung tissue may produce marked hypoxemia as fluid accumulates and impairs gas exchange. Disruption of the respiratory tract occurring from rupture or tearing of any of the respiratory structures prevents oxygen from reaching the alveoli, further impairing gas exchange.

Signs and Symptoms of Chest Injury

Important signs and symptoms of chest injury include the following:

- Pain at the site of injury
- Pain localized at the site of injury that is aggravated by or increased with breathing
- Bruising to the chest wall
- **Crepitus** (the sensation felt when broken bone ends grind together) with palpation of the chest
- Any penetrating injury to the chest
- Dyspnea (difficulty breathing, shortness of breath)
- Hemoptysis (coughing up blood)
- Failure of one or both sides of the chest to expand normally with inspiration (asymmetric movement)
- Rapid, weak pulse and low blood pressure
- Cyanosis around the lips or fingernail beds

After a chest injury, any change in normal breathing is a particularly important sign. A healthy, uninjured adult usually breathes 12 to 20 times per minute without difficulty and without pain. Fewer than 12 breaths/min or more than 20 breaths/min may indicate inadequate breathing, especially with poor tidal volume. Patients with chest injuries often have tachypnea (rapid respirations) and shallow respirations because it hurts to take a deep breath. They may also present with bradypnea (slow respirations) and labored respirations.

In an injured patient, dyspnea (difficulty breathing) has many causes, including airway obstruction, damage to the chest wall, improper chest expansion because of the loss of normal control of breathing, or lung compression because of accumulated blood or air. Dyspnea in an injured patient indicates significant compromise of lung function; therefore, prompt, vigorous support and transport are required.

As with any other injury, pain and tenderness are common at the point of impact as a result of a bruise or fracture. The normal process of breathing usually aggravates pain. Irritation of or damage to the pleural surfaces causes a characteristic sharp or stabbing pain with each breath when these normally smooth surfaces slide on one another. This sharp pain is called pleuritic pain or pleurisy.

Hemoptysis, the spitting or coughing up of blood, usually indicates that the lung parenchyma itself or the air passages leading to the lungs have been damaged. With a laceration of the lung, blood can enter the bronchial passages and is coughed up as the patient tries to clear the airway.

The presence or absence of a pulse in a specific location varies according to the nature and extent of injury. A rapid, weak pulse and hypotension (late sign) are the principal signs of hypovolemic shock, which can result from extensive bleeding from lacerated structures within the chest cavity. Shock following a chest injury may also result from insufficient oxygenation of the blood by the poorly functioning lungs. An absence of radial pulses may indicate severe hypotension. Tachycardia may indicate compensatory shock or hypoxemia. Bradycardia is generally an ominous sign. It may be the result of spinal damage or the final stage of shock in which the body is no longer able to compensate.

Changes in blood pressure also vary with the nature and extent of injury. Hypertension may be the result of increased sympathetic discharge, whereas hypotension is a sign of hypovolemia, relative hypovolemia (massive vasodilation), or late shock. Increased pressure on the myocardium decreases filling, resulting in a narrowed **pulse pressure** (the difference between the systolic blood pressure and the diastolic blood pressure). Loss of the peripheral pulse during inspiration suggests **pulsus paradoxus** (the systolic blood pressure drops more than 10 mm Hg during inspiration compared with expiration; also known as a paradoxical pulse) and the presence of **cardiac tamponade**. The patient may also present with hypothermia secondary to neurogenic shock if the injury involves the spinal cord.

Diaphoresis and pallor accompany peripheral vasoconstriction resulting from the sympathetic response of the autonomic nervous system to the injury. Cyanosis in a patient with a chest injury is a sign of inadequate respiration. The classic blue appearance around the lips and fingernail beds

indicates that blood is not being oxygenated sufficiently. Patients with cyanosis are unable to provide sufficient oxygen to the blood via the lungs and require immediate respiratory support and high-flow supplemental oxygen.

Many of these signs and symptoms occur simultaneously. When any one of them develops as a result of a chest injury, the patient requires prompt hospital care. Remember, the principal reason for concern about a patient who has a chest injury is that the person's body has no means of storing oxygen; it is supplied and used continuously, even during sleep. Any interruption in the oxygen supply can be rapidly lethal and must be treated aggressively.

Patient Assessment

Scene Size-up

When you arrive on the scene, your first responsibility is to ensure the safety of both you and your partner. Ensure the scene is safe to enter and that you are using the appropriate personal protective equipment.

Ensure you and your crew take standard precautions and wear, at a minimum, gloves, face mask, and eye protection. Put several pairs of gloves in your pocket for easy access in case your gloves tear or there are multiple patients with bleeding. Darker clothing may mask signs of bleeding, so you must remain vigilant, especially when the MOI suggests the patient may be bleeding.

Recognizing that a patient has sustained a significant MOI will allow you to develop an early index of suspicion for underlying injuries. Chest injuries are common in MVCs, falls, and assaults.

Words of Wisdom

Patients with gunshot or stab wounds to the chest should not be fully immobilized on a backboard. Instead, rapidly move and secure the patient to the stretcher and transport in a semi-Fowler position. A cervical collar may be applied if needed based on an additional MOI. Time is critical for these patients, and they should be transported as rapidly as possible to an appropriate trauma center.

After you identify the number of patients, triage those patients, and request any additional resources needed, then begin assessing your assigned patient. Consider the need for spinal immobilization.

Primary Survey

As you approach the patient, you will form a general impression of the patient's condition. It is important to note the patient's level of consciousness. Responsive patients may be able to tell you their chief complaint. Note not only what they say, but also how they say it.

Difficulty speaking may indicate several problems, and chest injury is an important one. Perform a rapid exam of the patient. Look for obvious injuries, the appearance of blood, and difficulty breathing. Look for cyanosis, irregular breathing, and chest rise and fall on only one side. Observe the neck, looking for accessory muscle use while breathing; also look for extended or engorged external jugular veins. The initial general impression will help you develop an index of suspicion for serious injuries and determine your sense of urgency for medical intervention. A good question to ask yourself is "How sick is this patient?" Patients with significant chest injuries will "look" sick and are often frightened or anxious.

If no obvious problems are seen, then begin an assessment to identify life threats (assess eXsanguinating hemorrhage, Airway, Breathing, Circulation, Disability, and Exposure [XABCDEs]). Addressing life threats begins with assessing airway and breathing unless life-threatening uncontrolled bleeding is present. Ensure the patient has a clear and patent airway. Normal breathing should be effortless, and any deviation from this pattern should be cause for concern. How you assess and manage the airway depends a great deal on whether you suspect the patient has a spinal injury. Patients with traumatic chest injuries may also have spinal injuries as a result of the MOI. Proper precautions should be taken when the potential for spinal trauma is present. Protect the spine early in your care, even if your assessment later confirms that there is no spinal injury.

Examine the neck for the presence of penetrating wounds and the position of the trachea. Palpate and note the presence of any subcutaneous emphysema.

Once you have determined the patient has a patent airway, determine whether breathing is present and adequate. With chest injuries, begin by inspecting for DCAP-BTLS (Deformities, Contusions, Abrasions, Punctures/penetrations/paradoxical movement, Burns, Tenderness, Lacerations, and Swelling), and look for equal expansion of the chest wall. Look for retractions around the ribs, neck, and clavicles, along with other evidence of respiratory distress. Visualize the region looking for deformities, such as asymmetry of the left and right sides of the chest or shoulder girdle, which may reveal the presence of multiple rib fractures, crush injuries, or significant chest wall injury. Identify discrete areas of contusion or abrasion to help pinpoint a specific point of impact. The presence of puncture wounds or other penetrating injuries suggests an open chest injury that should be managed accordingly. Be alert for associated burns, which may alter respiratory mechanics. Palpate for tenderness to localize the injury and identify the presence of fractures. Look for lacerations and local swelling. Apply this systematic approach to patient assessment to minimize the chance of missing a significant injury.

Listen with a stethoscope to each side of the chest. Absent or decreased breath sounds on one side usually indicate significant damage to a lung, preventing it from expanding properly. Be alert to the pattern of symmetric rise and fall of the patient's chest wall. If the chest wall does not expand on each side when the patient inhales, then the chest muscles may have lost their ability to function appropriately.

Loss of muscle function may be the result of a direct injury to the chest wall, or it may be related to an injury of the nerves that control those muscles. Also, check for **paradoxical motion**, an abnormality associated with multiple fractured ribs in which one segment of the chest wall moves opposite the remainder of the chest—for example, one part moves out with expiration and in with inspiration.

If you determine the patient has penetrating trauma, then address this life threat at once. Open chest injuries may interfere with the normal mechanics of breathing and can cause the patient's condition to worsen quickly. For quick initial care, you can immediately cover any open wounds with your gloved hand, and then apply an **occlusive dressing** to all penetrating injuries to the chest. Depending on local protocol, the dressing may be

taped on three sides to allow air to escape during exhalation. Administer oxygen via a nonrebreathing mask at 15 L/min. Provide positive-pressure ventilations with 100% oxygen if breathing is inadequate based on the patient's level of consciousness and breathing rate and quality. Remember, positive-pressure ventilation is a process of overcoming the normal physiologic functions; thus, if the patient has a pneumothorax (collapsed lung), this intervention may quickly exacerbate the injury. Be diligent with auscultation of breath sounds, and evaluate the effectiveness of your ventilatory support by looking for signs of circulation to the skin. Be aware of decreasing oxygen saturation (SpO_2) values because they may indicate hypoxia is developing. Watch for signs of an impending tension pneumothorax, such as increasingly poor compliance during ventilation.

Words of Wisdom

An impaled object should be removed only when it is in the cheek and interferes with breathing, or when it is in the chest and interferes with chest compressions. Otherwise, it should be stabilized in place.

Pay close attention to any changes in the patient's mental status. A decrease in the level of consciousness may indicate worsening of the condition or increasing hypoxia.

Assess the patient's pulse. Determine whether it is present and adequate. If the pulse is too fast or too slow, or if the skin is pale, cool, or clammy, then consider the patient to be in shock. You need to treat this condition aggressively to eliminate the cause and support the patient's circulatory system. Note that in the early stage of shock, the body compensates for blood loss by increasing the heart rate. Be alert for this change, especially if tachycardia is still present beyond a few minutes after the initial adrenaline rush from the incident or injury.

External bleeding may or may not be significant, but if it is considered life threatening, address this threat immediately. Control such bleeding with direct pressure and a bulky trauma dressing. Bleeding inside the chest can be significant and, as discussed earlier, can be a quick cause of death.

Auscultation of the heart sounds is another part of the circulatory assessment, though it may be

difficult to perform in the prehospital or ambulance setting. For patients with potential intrathoracic injuries, note whether their heart sounds are easily heard or whether they are muffled. The presence of muffled heart tones is an important diagnostic clue to the presence of a cardiac tamponade.

After auscultation, percuss the chest and note any abnormal findings. Recall, hyperresonance is a tympanic, drumlike sound that generally indicates the presence of air. When hyperresonance is heard on percussion of the chest, this finding suggests air in the pleural space, or a pneumothorax. Conversely, hyporesonance is a dull sound that generally indicates a solid or fluid, rather than air. Therefore, when heard on percussion of the chest, hyporesonance may suggest the presence of blood, or a hemothorax.

Note the presence of a scaphoid (hollow, boat-shaped) abdomen, which indicates the abdominal contents have shifted upward into the thoracic cage as a result of a ruptured diaphragm. If possible, then note whether bowel sounds are heard in the lower hemithorax; this also could indicate a ruptured diaphragm.

Note whether the jugular veins are distended (**FIGURE 31-8**). **Jugular venous distention (JVD)** suggests increased intravenous (IV) pressure, possibly resulting from a tension pneumothorax, volume

FIGURE 31-8 Jugular venous distention.

© Ferencga/Wikimedia Commons.

overload, right-side heart failure, or cardiac tamponade. Because true JVD is measured with the patient sitting in a 45° angle, it may be difficult to assess when spinal immobilization has been implemented. Nevertheless, a lack of JVD in the supine position in combination with other physical findings (eg, tachycardia, altered mental status, thready pulses, poor skin perfusion) may suggest a hypovolemic state.

Even if your assessment of the patient's circulatory status suggests hypovolemic shock, you should recognize that the cause may not lie within the thorax. Some patients with a combination of thoracic trauma and shock will have a significant hemorrhage within the chest, but others may experience hypovolemic shock secondary to intra-abdominal injury, neurogenic shock following a spinal cord injury, or cardiogenic shock due to myocardial infarction, for example.⁵ For this reason, after you complete the primary survey, manage any immediate life-threatening conditions, and prioritize the patient, you must obtain the patient's history and perform a complete physical exam to identify other significant injuries.

Priority patients are those who have airway, breathing, and/or circulation problems. Sometimes the priority is obvious, and the decision to transport quickly is also easy. At other times, what is happening outside the body may not provide obvious clues to the seriousness of what is happening inside the body. Pay attention to subtle clues such as the appearance of the skin, level of consciousness, or a sense of impending doom in the patient. These symptoms are not as dramatic as a large gash across the chest or bubbles coming out of a wound in the chest wall, but they can be equally important indicators of a life-threatening condition. When you find signs of poor perfusion or inadequate breathing, transport quickly and perform the remainder of the assessment en route to the emergency department (ED). A delay on the scene to perform a lengthy assessment will reduce the chances of survival for your patient. With chest injuries, when in doubt, transport rapidly to a hospital. **TABLE 31-1** lists the “deadly dozen” chest injuries.

History Taking

Depending on the severity of the injuries identified up to this point, history taking may need to be done en route to the ED.

TABLE 31-1 Life-Threatening Chest Injuries

Immediately life-threatening chest injuries that must be detected and managed during the primary survey:

1. Airway obstruction
2. Bronchial disruption
3. Diaphragmatic tear
4. Esophageal injury
5. Open pneumothorax
6. Tension pneumothorax
7. Hemothorax
8. Flail chest
9. Cardiac tamponade

Potentially lethal chest injuries that may be identified during the secondary assessment:

10. Thoracic aortic dissection
11. Myocardial contusion
12. Pulmonary contusion

Data source: Yamamoto L, Schroeder C, Morley D, Beliveau C. Thoracic trauma: the deadly dozen. *Crit Care Nurs Q*. 2005;28(1):22-40.

Once you have identified and treated life threats, further investigate the chief complaint and MOI, and obtain a history of the present illness (OPQRST-I: Onset, Provocation, Quality, Region/radiation/referral, Severity, Timing, Interventions prior to EMS arrival) and a past medical history (SAMPLE: Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury). Also obtain a history of the patient's mental status and include the following information when applicable:

- Dyspnea
- Chest pain
- Associated symptoms
 - Other areas of pain or discomfort
 - Symptoms before the incident
- History of cardiorespiratory disease
- Use of restraint in a MVC
- Any medications the patient may be taking (Remember, certain medications can mask compensatory mechanisms.)

Investigate associated signs and symptoms and pertinent negatives. If the patient was assaulted with a blunt object such as a bat, then further evaluate the spinal region for injury because the force may have been transferred through the body from the point of impact. If the patient fell from a great height and is reporting chest discomfort or dyspnea, then this may distract the patient from recognizing

fractures or bleeding from the extremities. Palpation of the chest will typically cause direct pain at the site of a fracture. When a patient reacts to the pain, make certain to verify where the pain was located relative to the area being touched.

Pertinent negatives when examining the chest include no associated shortness of breath, no rapid breathing, no absent or abnormal breath sounds, and no areas of deformity or abnormal movement. In a patient with a suspected spinal cord injury, equal expansion of the chest and movement of the rib cage and the diaphragm can confirm to you that there is nerve conduction to that region of the body.

Obtaining a SAMPLE history from a patient with a chest injury may not seem very important, but a basic evaluation of signs and symptoms; allergies; medications; pertinent medical history, including respiratory or cardiovascular disease; and last oral intake should be attempted if time permits. The events leading to the emergency should also be identified. Questions about the events surrounding the incident should focus on the MOI: the speed of the vehicle or height of the fall; the use of safety equipment, such as a helmet, airbag, seat belt, or life jacket; the type of weapon used; the number of penetrating wounds; and so on. A SAMPLE history can be obtained quickly in most situations and can certainly be obtained while accomplishing other tasks. However, if the patient becomes unresponsive, it will no longer be possible to obtain the information.

Secondary Assessment

During the secondary assessment, look for injuries with the potential to compromise the management of the ABCs—namely, aortic transections, great vessel injuries, bronchial disruptions, myocardial contusions, pulmonary contusions, simple pneumothoraces, rib fractures, and sternal fractures.

In a patient who has an isolated injury to the chest with a limited MOI, such as in a stabbing, focus your assessment on the isolated injury, the patient's complaint, and the body region affected. However, it is important in patients with a chest injury not to focus only on a chest wound. With significant trauma, you should quickly assess the entire patient from head to toe. While you are assessing the skin, look for ecchymosis and other evidence of trauma. Ensure wounds are identified and control of the

bleeding has been established. Note the location and extent of the injury. Assess all underlying systems. Examine the anterior and posterior aspects of the chest wall, and be alert to changes in the patient's ability to maintain adequate respirations.

Repeat the rapid full-body scan looking for DCAP-BTLS to determine any changes in thoracic injuries previously discovered and to search for problems not previously found. You may have symmetric chest rise in the primary survey only to discover that upon reassessment, chest rise is unequal due to the progression of a pneumothorax. Some signs are not initially prevalent but become more pronounced as damage progresses. It is for this reason that it is necessary to reassess those areas already covered in the primary survey.

If you have not already done so, obtain a full set of vital signs, including pulse rate, blood pressure, respirations, oxygen saturation, mental status, skin condition, and pupils. Each of these is considered a sign indicating how the patient is tolerating the injuries. Consider these signs as a window to the functioning of the vital organs. This baseline set of vital signs will be used to evaluate changes in the patient's condition. Because patients with significant chest injury have the potential for life-threatening deterioration in their condition, they should be re-evaluated every 5 minutes or less. This will allow you to quickly recognize changes in the vital sign numbers or trends.

If you find an accelerated pulse rate or respiratory rate, then the chest injury may be causing either a decrease in available oxygen (hypoxia) or blood loss that results in a decreased number of red blood cells that can carry oxygen (hypoxemia). The increased respiratory rate is often associated with an obvious increase in work of breathing. This can be identified by noting increased use of the accessory muscles in the face, neck, and chest to assist in the movement of air. In the later stages of injuries, the pulse rate can slow as the myocardium becomes starved for oxygen and the body is no longer able to keep up with the demands. The respiratory rate may decrease as the brain becomes starved for oxygen and overloaded with carbon dioxide and other waste products. These are usually signs of impending cardiopulmonary arrest. In the case of increasing pressure on the heart from the pleural space or the pericardial space, the blood pressure may exhibit a narrowing pulse pressure as the systolic and

diastolic pressures come closer together. This is a result of the inability of the heart to fill with an adequate volume of blood and contract normally.

Using diagnostic tools—most commonly the pulse oximeter—to evaluate the effectiveness of the respiratory system is especially important with an injury or insult to the thorax because the injury can decrease the amount of available oxygen within the blood. The pulse oximeter monitors the oxygen saturation of hemoglobin by directing a beam of infrared light through the capillary beds of an area (such as a finger) between two probes. The light received after passing through the capillary bed is measured as a percentage that indicates how well the hemoglobin in the red blood cells is coated or saturated with oxygen. In normal circumstances, the hemoglobin is saturated with oxygen, and the SpO_2 is greater than 94%. However, if the patient has

a decreased number of red blood cells, a damaged pump (heart), or a pulmonary contusion, less oxygen is available to be absorbed by the hemoglobin, resulting in a decreased SpO_2 .

However, when there is carbon monoxide in the patient's bloodstream, the pulse oximeter may give misleading results. Carbon monoxide binds to hemoglobin with a higher affinity than does oxygen. Because the oximeter can only recognize that the hemoglobin is bound to something and cannot distinguish between hemoglobin bound to carbon monoxide and hemoglobin bound to oxygen, the values produced by pulse oximetry can

Words of Wisdom

While pulse oximetry can evaluate the effectiveness of oxygenation, it cannot measure the amount of oxygen being consumed by a patient's cells during cellular metabolism. Measuring carbon dioxide levels is a more accurate method of determining oxygen consumption. Carbon dioxide is the by-product of aerobic cellular metabolism and reflects the amount of oxygen being consumed during the process. *Metabolism* refers to the chemical reactions that occur in the body or cells to maintain life. There are two noninvasive methods in which carbon dioxide is monitored in the field: capnometry and capnography. Capnometry typically consists of a disposable or electronic device that provides you with a means of measuring exhaled carbon dioxide. Capnography not only includes measuring exhaled carbon dioxide, it also provides a waveform based on serial measurements. Capnography can provide information about a patient's ventilatory status, circulation, and metabolism. Capnography can also serve as an indicator of chest compression effectiveness and detect return of spontaneous circulation. It can provide this information because blood must circulate through the lungs for carbon dioxide to be exhaled and measured. These devices are typically used by paramedics in the prehospital setting as the gold standard for confirming endotracheal tube placement, to optimize an intubated patient's ventilatory rate, and to avoid inadvertent hyperventilation of head-injured patients, which has been linked to poor outcomes. For more information, refer to Chapter 10, *Patient Assessment*.

Assessment Pearls

- Perform a thorough assessment, paying particular attention to neck veins:
 - **Tension pneumothorax = Distended neck veins.** Pressure in the chest is preventing blood return to the right ventricle and causing it to back up in the neck veins.
 - **Cardiac tamponade = Distended neck veins.** Pressure in the pericardial sac is preventing blood return to the right ventricle and causing it to back up in the neck veins.
 - **Hemothorax = Flat neck veins.** Blood is filling up the thoracic cavity, and there is not enough for blood to back up in the neck veins.
- Treatment for a flail segment involves splinting internally via positive-pressure ventilation. If the patient is alert, the patient may hold a pillow or folded blanket against the area for comfort, but no external bandaging should be applied.
- Note lung compliance when ventilating a patient with a chest injury. Difficulty ventilating may indicate a buildup of pressure in the chest. If the patient has a pneumothorax, this difficulty ventilating may be your first sign of tension developing.
- Call early for advanced life support (ALS) backup if a pneumothorax is suspected. Tension can develop rapidly, especially if you are ventilating the patient.
- Use an occlusive dressing on any upper abdominal wound. Any puncture from the umbilicus upward may penetrate the thoracic cavity.
- Remember that treatment for commotio cordis is early defibrillation.
- Use end-tidal carbon dioxide (ETCO_2) measurements! Pulse oximetry is not accurate when the patient shows signs of hypoperfusion.

be misleading, potentially resulting in your under-treating the patient. Therefore, it is generally advisable to use the pulse oximeter on any patient with a chest injury to establish a baseline measurement and to help you recognize any downward trends that indicate the patient's condition is worsening. If you suspect carbon monoxide exposure that may be causing a falsely elevated pulse oximetry value, provide supplemental oxygen regardless of the measured SpO_2 level.

Reassessment

When you are reassessing the patient with thoracic trauma, reassess the patient's vital signs, oxygenation, circulatory status, and breath sounds. Reassess the chief complaint to identify and treat any changes in the patient's condition and recheck interventions. Reevaluate the patient every 5 minutes or less. Because the progression from pneumothorax to tension pneumothorax can occur quite rapidly, all patients with a presumptive diagnosis of a pneumothorax should be considered to be in an unstable condition and should be reassessed frequently for worsening dyspnea, tachycardia, and developing JVD. Similarly, other thoracic injuries may suggest the presence of more serious underlying pathologic conditions. Because these injuries may have been overlooked during the initial examinations, you need to maintain a high degree of suspicion during the on-scene treatment and transport of these patients.

Communicating with hospital staff early when the patient has a significant MOI to the chest can help them be prepared with appropriate equipment and personnel when you arrive. If a penetrating injury is present, then describe it in your verbal report, along with the interventions that you applied. If a flail segment is present, then hospital staff may be able to offer assistance on how to manage it. Your documentation should be complete and thorough. Describe all injuries and the treatment given. Remember, your documentation is your legal record of what happened.

Emergency Medical Care

Stabilizing the ABCs is the primary management concern for all patients, and thoracic trauma is no exception. Evaluate the patient's airway and

respiratory status while maintaining cervical spine immobilization. Be prepared to suction the patient, consider placing an oropharyngeal or nasopharyngeal airway, and consider definitive airway management.

Whenever you suspect significant bleeding, administer high-flow oxygen. If needed, provide assisted ventilation using a bag-mask device with high-flow oxygen. If you find penetrating trauma to the chest wall, then place an occlusive dressing over the wound. Use caution to avoid increasing the patient's work of breathing and pain. Be prepared to provide positive-pressure ventilation if the patient's respiratory efforts are not effective. If the patient has signs of hypoperfusion, then treat for shock and provide rapid transport to the appropriate hospital. Do not delay transport of a seriously injured trauma patient to complete non-life-saving treatments such as splinting extremity fractures; instead, complete these types of treatments en route to the hospital. Keep the patient warm. Maintain circulation and gain IV access. Establish at least one large-bore IV catheter, preferably two, and administer a 20-mL/kg bolus of an isotonic crystalloid solution to maintain adequate perfusion. With thoracic trauma, your goal is to maintain radial pulses. Titrate fluid administration to a systolic blood pressure of 80 to 90 mm Hg. Increasing blood pressure above this point may increase bleeding into the chest and worsen the patient's condition. Always follow local protocols.

Words of Wisdom

Increasing the patient's blood pressure excessively may increase bleeding, causing a more rapid deterioration of the patient's condition. For this reason, you should titrate IV fluid rates to maintain perfusion (radial pulses) without significantly raising the blood pressure.

Call for paramedic support, if available, in a timely manner if there is any suspicion of impending cardiac arrest or a potential need for chest decompression. In-hospital management may include a tube thoracostomy for a hemothorax or pericardiocentesis for cardiac tamponade. Early recognition of signs and symptoms and early transport can significantly increase your patient's chance of survival.

Pathophysiology, Assessment, and Management of Specific Emergencies

This section covers specific thoracic injuries that fall into the following categories: chest wall injuries, lung injuries, myocardial injuries, vascular injuries, and other injuries such as diaphragmatic injury, esophageal injury, tracheobronchial injury, and traumatic asphyxia.

Special Populations

The incidence of rib fractures varies with age. The ribs of children are pliable, so the ribs may injure underlying structures without being fractured. Significant force can be transmitted directly to underlying organs in pediatric patients, causing significant blunt trauma. In older adult patients, the frail nature of the bones makes the ribs more likely to fracture.

Rib Fractures

Rib fractures are infrequent in children because of the pliability of their thoracic cage. Rib fractures occur most often in older patients, who have lost pliability and whose bones may be very brittle (for example, because of osteoporosis). Because the upper four ribs are well protected by the bony girdle of the clavicle and scapula, a fracture of one of these upper ribs is a sign of a very severe MOI. A significant force is required to cause fractures and may be indicative of other injuries. Morbidity and mortality rates increase with age, number of fractures, and location of the fractures.

A fractured rib may potentially lacerate the surface of the lung, causing a pneumothorax, tension pneumothorax, hemothorax, or hemopneumothorax. One sign of this complication is a “crackly” feeling to the skin in the area (also called subcutaneous emphysema), which indicates that air escaping from a lacerated lung is leaking into the subcutaneous layer of the chest wall. Ensure you communicate this finding to hospital personnel.

Rib fractures are most often caused by blunt trauma, with the fracture occurring at midshaft owing to the bowing effect of the ribs. Ribs four

through nine are the ones most often fractured because they are thinner and poorly protected. The patient will usually present using an arm to splint the injury and with shallow respirations to decrease chest movement, thereby decreasing pain. Unfortunately, decreasing chest excursion also decreases tidal volume, minute volume, and the amount of oxygen available for gas exchange. The development of atelectasis, or collapse of the alveoli, caused by trauma also decreases the surface area for gas exchange. The result is a ventilation/perfusion mismatch. The circulatory system is intact, but the amount of lung tissue available for gas exchange has been greatly diminished. The mismatch may also occur when inadequate perfusion is present. An underlying pulmonary or cardiac contusion or an intercostal vessel injury may hinder perfusion, leading to hypoxemia that is just as severe.

When the first and second ribs are injured by severe trauma, the result may be a ruptured aorta, tracheobronchial tree injury, or vascular injury. Trauma to the left lower rib may contribute to injury of the spleen, and trauma to the right lower rib may cause liver injury. Multiple rib fractures may lead to atelectasis, hypoventilation, inadequate cough, and pneumonia. With a posterior fracture, the fifth through the ninth ribs are the most frequently injured. Owing to their location in the thorax, lower rib fractures are associated with spleen and kidney injuries. The floating ribs, because they are well protected by the strong abdominal musculature, are rarely fractured; therefore, injury to these ribs suggests a severe MOI and a strong potential for other life-threatening injuries.

Regardless of the position, any rib fracture puts the patient at risk for multiple injuries. It is imperative to maintain a high index of suspicion, even if the patient appears to have no visible injury.

Patients with one or more fractured ribs will report localized tenderness and pain on breathing, typically during inspiration. This pain is the result of the broken ends of the fractured rib rubbing against each other with each inspiration and expiration, deep breathing, and/or coughing. Patients will tend to avoid taking deep breaths, breathing rapidly and shallowly instead. They will often hold the affected portion of the rib cage in an effort to minimize the discomfort. On palpation, the patient may present with point tenderness over the site, crepitus or an

audible crunch, and pain when anteroposterior pressure is applied.

Managing rib fractures focuses on managing the ABCs and evaluating the patient for other, more lethal injuries. Administer supplemental oxygen and gently splint the patient's chest wall by having the patient hold a pillow or blanket against the area; this measure may allow the patient to take deeper breaths—something that should be encouraged despite the pain. IV analgesics may also assist in this regard. If permitted by medical control, then you can administer nitrous oxide.

Words of Wisdom

Considering the potential seriousness of chest injuries, always keep an automated external defibrillator (AED) ready when responding to a call for a chest injury. Be ready to apply the AED should cardiac arrest occur.

Flail Chest

Ribs may be fractured in more than one place. If two or more adjacent ribs are fractured in two or more places or if the sternum is fractured along with several ribs, then a segment of the chest wall may be detached from the rest of the thoracic cage, producing a free-floating segment⁶ (FIGURE 31-9). This

FIGURE 31-9 When two or more adjacent ribs are fractured in two or more places, a flail chest results. A flail segment will move paradoxically when the patient breathes.

© Jones & Bartlett Learning.

condition is known as **flail chest**. The most common cause of a flail segment is a MVC, but it may also be caused by falls from significant heights, industrial accidents, or assault. Significant chest trauma is required to cause a flail chest. When flail chest is present, patient mortality averages 16%, often because of associated injuries.⁷ Mortality also increases with advanced age, seven or more fractured ribs, three or more associated injuries, shock, and head injuries.⁸

In what is called paradoxical motion, the detached portion of the chest wall moves in the opposite direction of normal—that is, it moves in instead of out during inhalation, and it moves out instead of in during expiration. This occurs because of negative pressure that has built up in the thorax. Breathing with a flail chest can be extremely painful and often does not allow for adequate oxygenation. Paradoxical motion is usually minimal because of muscle spasm. The patient will breathe as shallowly as possible to decrease movement of the thorax and, therefore, decrease pain, but this decreases ventilation. Respiratory failure in a patient with a flail chest generally results from other associated injuries. A pulmonary contusion resulting from a flail segment will impair gas exchange, leading to hypoxia and hypercapnia.

The blunt force trauma that causes the flail segment can also produce a **pulmonary contusion**, an injury to the underlying lung tissue that inhibits the normal diffusion of O_2 and CO_2 . If the blunt force that fractures the ribs drives bone fragments farther into the body, then a pneumothorax or hemothorax may result. In addition, the pain associated with the fractures may prevent the patient from taking in adequate tidal volume because the patient is consciously trying to minimize the movement of that segment of the chest. This “self-splinting” action uses the intercostal muscles and purposefully limits chest wall movement to minimize pain. Unfortunately, this action further limits the pulmonary system's ability to compensate for the injury.

Flail chest is a serious condition and suggests impact with a force that is significant enough to

Words of Wisdom

With flail chest injuries, pulmonary contusion is often the primary cause of hypoxemia.

cause other serious internal damage. When flail chest is suspected, expose and examine the chest for DCAP-BTLS. Look for any chest wall contusions, signs of respiratory distress and accessory muscle use, and any paradoxical motion. The patient may also present with pleuritic chest pain and with pain and splinting of the affected side. Note any areas of crepitus on palpation of the thorax. Tachypnea and tachycardia may also be present and are signs of inadequate oxygenation.

Typical management of flail chest is to first assess the need for positive-pressure ventilation, then administer oxygen. If ventilations are inadequate (or the ETCO_2 measurement reveals that the patient has hypercapnia), then you may use positive-pressure ventilation (via a bag-mask device or continuous positive airway pressure [CPAP]) as well as positive end-expiratory pressure (PEEP) when you are assisting ventilations for the patient. In the past, treatment included splinting of the flail segment with bulky dressings; however, restricting chest wall movement is no longer recommended.

Controversy

Stabilization of a flail segment is a controversial issue. Current guidelines suggest that positive-pressure ventilation, when appropriate, provides internal stabilization and increases oxygenation and ventilation for managing a pulmonary contusion. Splinting as previously recommended is of little to no value and may in fact limit ventilation. In the trauma center, some studies have shown patients may benefit from early operative stabilization that may possibly reduce further acute complications.⁹ Always follow local protocols.

Sternal Fracture

Sternal fracture may occur in patients experiencing blunt chest trauma—for example, when the sternum strikes the steering wheel or dashboard during deceleration. A blow significant enough to fracture the sternum causes severe hyperflexion of the thoracic cage. Isolated sternal fracture has a mortality rate that rises with additional injuries and as people age (17% mortality for persons younger than 55 years versus 27% mortality for those older than 55 years).¹⁰ If sternal fracture is present, then myocardial or lung injury is also very likely.

Morbidity and mortality are generally the result of associated injuries.¹¹ Enough force to fracture the sternum may also result in pulmonary and myocardial contusions, flail chest, vascular disruption of thoracic vessels, intra-abdominal injuries, and head injuries. It is rare for the fracture to be displaced posteriorly and directly impinge on the heart or vessels.

When a sternal fracture is present, expect to find localized pain and tenderness over the sternum, along with crepitus on palpation. The patient's presentation or MOI may be clues to the presence of a sternal fracture. Tachypnea is a common finding, and there may be electrocardiographic changes associated with a myocardial contusion.

Words of Wisdom

The sternum is a thick bone. If the thorax receives enough force to fracture the sternum, then you must assume the same force was transmitted to the heart, great vessels, lungs, and diaphragm.

When you are managing a sternal fracture, you should focus on maintaining a good respiratory status and monitoring for respiratory and/or cardiovascular changes. Provide positive-pressure ventilations as needed, but do not use overly aggressive ventilations that further exacerbate injuries. Establish IV access, but provide fluid sparingly (maintain radial pulses). Administer an isotonic crystalloid solution to maintain a systolic blood pressure of 80 to 90 mm Hg. Elevate the head of the long backboard to help reduce pressure in the thoracic cavity and facilitate lung expansion.

Clavicle Fracture

The clavicle, or collarbone, is one of the most commonly fractured bones in the body. Fractures of the clavicle occur most often in children when they fall on an outstretched hand. They can also occur with crushing injuries of the chest. A patient with a fracture of the clavicle will report pain in the shoulder and will usually hold the arm across the front of the body.

Fractures of the clavicle can be splinted effectively with a sling and swathe. Information about fractures of the clavicle, scapula (shoulder

blade), and acromioclavicular joint can be found in Chapter 33, *Orthopaedic Injuries*.

Commotio Cordis

If the thorax receives a direct blow during the critical portion of the heart's repolarization phase, then the result may be immediate cardiac arrest. This phenomenon, termed **commotio cordis**, may occur after patients are struck in the chest with softballs, baseballs, bats, snowballs, fists, and even kicks during kickboxing. This condition is more commonly seen in children because the chest wall is more flexible and does not dissipate the force as well as an adult's body, leading to greater force absorbed by the heart. Commotio cordis is ultimately the result of the chest wall impact directly over the heart, especially directly over the left ventricle. Impacts to the chest that are not directly over the heart will not cause commotio cordis. The affected patient may present with ventricular fibrillation that responds positively to early defibrillation if provided within the first 3 minutes. For this reason, public access to defibrillators in schools and sports venues is essential.

Patients who are unresponsive, apneic, and pulseless may be experiencing commotio cordis. Many of these patients are cyanotic, and tonic-clonic (grand mal) seizures have been evident in some. Chest wall contusions and localized bruising that correspond to the site of chest impact are also indicators.

Increased awareness of this condition and preparation such as cardiopulmonary resuscitation (CPR) and AEDs being accessible at sporting events have greatly increased survival rates; conversely, factors such as delays in CPR and AED access of more than 3 minutes may decrease survival rates significantly.¹² ALS treatments must follow standard advanced cardiovascular life support (ACLS) guidelines for sudden cardiac arrest, and treatments of the underlying rhythm must be initiated early if successful resuscitation is to occur. Public awareness, CPR, AED access, and protective gear are all necessary elements to decrease the occurrence and improve survivability of this type of event.

Simple Pneumothorax

In any chest injury, damage to the heart, lungs, great vessels, and other organs in the thorax can

FIGURE 31-10 Pneumothorax occurs when air leaks into the space between the pleural surfaces from an opening in the chest wall or the surface of the lung. The lung collapses as air fills the pleural space.

© Jones & Bartlett Learning.

be complicated by the accumulation of air in the pleural space. This accumulation causes a serious condition called a **pneumothorax** (commonly called a collapsed lung). In this condition, air enters through a hole in the chest wall or the surface of the lung as the patient attempts to breathe, causing the lung on that side to collapse as pressure continues to build in the pleural space (**FIGURE 31-10**). As a result, blood that passes through the lung is not oxygenated, and hypoxia can develop. Depending on the size of the hole and the rate at which air fills the cavity, the lung may collapse in a few seconds or a few hours. The larger the hole, the more rapidly the lung will collapse. Delayed or improper treatment of a simple pneumothorax may lead to a tension pneumothorax, discussed later. Most low-velocity wounds self-seal, remedying the problem. The lungs are situated in the thoracic cavity such that at any point they are only 1 to 3 cm away from the chest wall. In a simple pneumothorax, there may only be a small accumulation of air and pulmonary function may remain adequate. The internal wound allows air to enter the pleural space. Small tears often seal themselves, and the patient experiences only minor discomfort. However, larger tears may progress.

Some people are born with or develop weak areas on the surface of the lungs. Occasionally, such a weak area will rupture spontaneously, allowing air to leak into the pleural space. Usually this

event, called **spontaneous pneumothorax**, is not related to trauma, but simply happens with normal breathing. The patient experiences sudden, sharp chest pain and increasing difficulty breathing. The affected lung collapses, losing its ability to expand normally. The amount of pneumothorax that develops varies, as does the amount of respiratory distress the patient experiences. You should suspect a spontaneous pneumothorax in a patient who experiences sudden sharp chest pain and shortness of breath without a specific known cause. Young men who are tall and thin seem to be at an increased risk for a spontaneous pneumothorax, especially if they have recently traveled by air.¹³ Both a pneumothorax (an accumulation of air) and a hemothorax (an accumulation of blood) occur in 80% of all cases of penetrating chest trauma.¹⁴

A patient who takes a deep breath just before blunt trauma to the chest may experience the **paper bag syndrome**, or paper bag effect. On impact, the lungs rupture like a paper bag that has been blown up and popped with your hand.

If the patient is standing, then air will accumulate in the apices. You should auscultate the apices first for diminished breath sounds. If the patient is supine, then air accumulates in the anterior portion

of the chest. As air accumulates, it forces the structures of the mediastinum toward the opposite side of the chest, dragging the trachea along. Although you may note the trachea tugging away from the affected side, tracheal deviation is a very late sign and is not seen in most cases. Compression of the lungs, myocardium, and great vessels cause a ventilation/perfusion mismatch because air is unable to enter the lungs and blood is unable to circulate.

The presentation and physical findings in a patient with a simple pneumothorax depend on the size of the pneumothorax and the degree of resulting pulmonary compromise. With a small pneumothorax, the patient may report only mild dyspnea and pleuritic chest pain on the affected side, and in young and fit patients, the simple pneumothorax may be well tolerated.

Patients with a simple pneumothorax may present with tachypnea and tachycardia as a result of hypoxia. If their conditions progress, respiratory distress increases and breath sounds may be decreased or absent on the affected side. Chest wall movement decreases as pressure increases, and hyperresonance can be detected with percussion. The patient may also experience dyspnea, chest pain that is referred to the shoulder or arm on the

YOU are the Provider

Part 3

While you are performing the primary survey on your patient, your partner tells you that the other patient was not injured and is refusing care. You ask your partner to retrieve the spinal immobilization equipment. The motocross safety official arrives, and you assign him to provide manual stabilization of the head as you begin to remove the patient's shirt to expose any possible injuries. As you remove the chest protector and shirt, you notice pain and tenderness over the sternum, with some possible crepitus as well. The patient denies having any head or neck pain, so you decide to remove his helmet to enable proper alignment on the backboard.

Recording Time: 5 Minutes

Respirations	32 breaths/min, shallow
Pulse	Strong and regular, 120 beats/min
Skin	Warm and dry
Blood pressure	98/55 mm Hg
Oxygen saturation (SpO₂)	97% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- What are some possible causes of this patient's dyspnea?
- Does this patient require rapid transport to the hospital?

Words of Wisdom

Percussion of the chest produces hyperresonance when the thorax is full of air, and hyporesonance, or dullness, when it is full of blood.

affected side, and pleuritic chest pain. The patient may also present with subcutaneous emphysema, signs of hypovolemia, or cardiac dysrhythmias.

As the pneumothorax increases in size, the degree of compromise also increases. Patients with larger pneumothoraces will report increasing dyspnea and demonstrate signs of more serious respiratory compromise and hypoxia: agitation, altered mental status, tachypnea, tachycardia, cyanosis, lowered pulse oximetry readings, pulsus paradoxus (a drop in blood pressure on inspiration greater than 10 mm Hg), and absent breath sounds on the affected side.

When pneumothorax is suspected, immediately cover any open wounds with an occlusive dressing. Maintain the ABCs. Use positive-pressure ventilation sparingly because excessive pressure may result in a tension pneumothorax. The most critical intervention for these patients is conducting repeated assessments to ensure the injury has not progressed to a tension pneumothorax. If signs and symptoms show the development of a tension pneumothorax, then you may need to “burp” or remove the dressing to allow for the release of the trapped air within the thoracic cage. Most pneumothoraces result from a small pulmonary injury that seals itself off, preventing further air loss. For those that do progress, however, rapid recognition and management of this condition can be lifesaving. Call for paramedic backup for treatment of potential cardiac dysrhythmias and/or a tension pneumothorax.

Open Pneumothorax

An **open pneumothorax** occurs with penetrating trauma to the chest. Profound hypoventilation could result, and death may occur quickly if care is delayed.

With an open pneumothorax, an open injury in the chest wall allows for communication between the pleural space and the atmosphere, limiting the development of negative intrapleural pressure on

inspiration and resulting in collapse of a portion of the lung. Of course, this also means the affected lung does not have the ability to ventilate. Hypoventilation results from the increased pressure and decreased lung surface area available for gas exchange to occur, and hypoxia occurs as less oxygen is available for gas exchange.

Air enters the pleural space during the inspiratory phase. Negative pressure draws air into the lungs and through the opening in the chest wall. Air may exit during the exhalation phase or may remain trapped in the pleural space. Resistance to air flow through the respiratory tract may be greater than through the open wound, resulting in an ineffective respiratory effort. A one-way flap valve may let air in but not out, resulting in a buildup of pressure in the pleural space. Direct lung injury may be present if the lung parenchyma was penetrated. The vena cava may become kinked from swaying of the mediastinum as pressure builds, resulting in decreased preload and a subsequent decrease in cardiac output.

The presence of a defect in the chest wall or penetrating injury should be noted as the patient is exposed during the primary survey. Air motion may be detected at the site of the defect as the patient inhales and exhales. A sucking sound may be heard on inhalation as air is drawn into the thoracic cavity through the opening in the chest wall. For this reason, an open or penetrating wound to the chest wall is often called a **sucking chest wound** (**FIGURE 31-11**). Tachycardia and tachypnea increase in relation to the level of respiratory distress as intrathoracic pressure increases and oxygenation decreases. Subcutaneous emphysema may also be found, along with decreased breath sounds on the affected side. The patient may also present with signs of hypovolemia and cardiac dysrhythmias.

Sucking chest wounds must be treated immediately. The injury should first be converted to a closed injury to prevent further expansion of the pneumothorax. To do so, immediately place your gloved hand over the injury and then replace that hand with an occlusive dressing or a commercial chest seal (**FIGURE 31-12**). Because of the possibility that an underlying lung injury may continue to contribute to the pneumothorax, this dressing should be secured on three sides to facilitate the release of increased pressure, should it develop.

FIGURE 31-11 With a sucking chest wound, air passes from the outside into the pleural space and back out with each breath, creating the sucking sound.

© Jones & Bartlett Learning.

Managing an open pneumothorax is the same as managing a simple pneumothorax. When you use an occlusive dressing to seal an open chest wound, record the type of material used, whether three or four sides were sealed, and any changes noted in skin color, vital signs, breath sounds, and particularly the patient's level of respiratory distress after application of the dressing. Monitor for changes and "burp" the dressing if the patient presents with any signs of increasing distress.

Words of Wisdom

If a patient with an open chest wound sealed with an occlusive dressing shows signs of developing tension, then raise one side of the dressing to allow air to escape. This is known as burping the dressing.

Tension Pneumothorax

A **tension pneumothorax** may be the result of blunt or penetrating trauma (**FIGURE 31-13**). This can occur when there is a significant ongoing air accumulation in the pleural space. The increase in pressure causes the collapse of the affected lung and pushes the mediastinum (the central part of the chest

A

B

FIGURE 31-12 A commercial occlusive dressing may be used to seal all four sides of a sucking chest wound. **A.** An Asherman Chest Seal, which is vented. **B.** A HALO Chest Seal, which is unvented.

© Jones & Bartlett Learning.

containing the heart and the great vessels) into the opposite pleural cavity. This prevents blood from returning through the venae cavae to the heart, decreasing cardiac output, causing shock, and ultimately resulting in death.

Tension pneumothorax can result from a defect in the airway that allows for communication with the pleural space. This defect may be the result of blunt trauma in which a lung is penetrated by a fractured rib (most common), a sudden increase in intrapulmonary pressure culminating in rupture of pulmonary structures, or bronchial disruption from shearing forces, allowing air to enter the pleural space and increase the intrathoracic pressure.

The classic signs of a tension pneumothorax are an absence of breath sounds on the affected side, unequal chest rise, pulsus paradoxus, tachycardia and dysrhythmias such as progression to

FIGURE 31-13 A tension pneumothorax can develop if a penetrating chest wound is bandaged tightly and air from a damaged lung cannot escape. The air then accumulates in the pleural space, eventually compressing the heart and great vessels. If a dressing sealed on four sides with no vent is used, then monitor for signs of tension pneumothorax developing and prepare to vent one side of the dressing.

© Jones & Bartlett Learning.

ventricular tachycardia and ventricular fibrillation, JVD, narrow pulse pressure, and tracheal deviation. Whereas tachycardia may not be a unique finding in the trauma patient, tension pneumothorax induces this change—not because of a hypovolemic state, but rather because of the inability of blood to easily return to the heart from the venous system. The increasing pressure within the thoracic cage leads to the accumulation of blood within the great vessels just outside the thoracic cage. As the pressure is translated into the most superficial of these veins, the jugular veins, they become distended with blood. Such JVD is usually a late sign of tension pneumothorax.

During normal inspiration, the negative pressure within the chest increases blood return to the heart, thus increasing preload and, therefore, cardiac output. In tension pneumothorax, the effect on preload of inspiration is blunted because of compression on the great vessels, and a decrease in cardiac output results.

Because of the mediastinal shift caused by the increasing pressure, palpate or visualize the trachea, which may show a deviation of the trachea away from the affected side. However, this typically very late finding in a tension pneumothorax may

not be present despite the rapid decompensation of the patient's clinical status. For this reason, you must be vigilant in watching for the cardiopulmonary findings associated with a tension pneumothorax and not rely on the presence of all the classic physical findings in making the diagnosis.

The accumulation of air within the pleural space decreases the lung volume and diminishes the breath sounds on the affected side when you auscultate the chest. Because air causes the loss of breath sounds on that side, the chest will be resonant (like a bell) when percussed, as opposed to the dull sensation expected with fluid or blood buildup.

A patient with a developing or early tension pneumothorax often reports pleuritic chest pain and dyspnea because of the injury and the collapsing lung. The resulting hypoxia in a patient with a developing tension pneumothorax may cause the patient to become anxious, tachycardic, tachypneic, and even cyanotic.

Hypotension, a late finding of tension pneumothorax, should not be used to either confirm or exclude the possibility of a tension pneumothorax. Its presence may suggest the pneumothorax has produced such significant pressure as to severely impede preload, or it may represent a simultaneous

shock state due to other injuries. A normal blood pressure suggests when other signs of a tension pneumothorax are present, the heart is adequately compensating for the diminished venous return.

In a patient with tension pneumothorax, you should first focus on maintaining the ABCs. Inspect the chest and cover any open wounds with an occlusive or nonporous dressing. If signs of developing tension are present, then lift one corner of the dressing to allow air to escape. In the event of a closed tension pneumothorax, call early for paramedic backup to perform a needle chest decompression and for treatment of possible dysrhythmias or transport rapidly to a trauma center, depending on which is faster.

Words of Wisdom

Assessment findings in a patient experiencing a pneumothorax that is developing tension include the following:

- Unilaterally decreased or absent breath sounds
- Unequal chest rise
- Dyspnea
- Tachypnea
- Respiratory distress
- Extreme anxiety
- Cyanosis
- Bulging of the intercostal muscles
- Tachycardia
- Hypotension
- Narrowed pulse pressure
- Subcutaneous emphysema
- Jugular venous distention
- Tracheal deviation
- Hyperresonance
- Pulsus paradoxus

Tracheal deviation and JVD are late signs and should not be used as determining factors to initiate invasive treatment. Moreover, JVD may not occur at all in patients with hypovolemia.

Hemothorax

A hemothorax occurs when the potential space between the parietal and visceral pleura is violated and blood begins to accumulate within this space (**FIGURE 31-14**). Although it is most commonly caused by tears of lung parenchyma, a hemothorax may sometimes result from penetrating wounds that puncture the heart or major vessels within the

FIGURE 31-14 A. A hemothorax is a collection of blood in the pleural space produced by bleeding within the chest. **B.** When blood and air are present, the condition is called a hemopneumothorax.

© Jones & Bartlett Learning.

mediastinum or from blunt trauma with deceleration shearing of major vessels or of intercostal vessels. Rib fractures and injuries to the lung parenchyma are the most common sources of injury in cases of hemothorax. Other causes include injury to the liver, spleen, aorta, internal mammary arteries, intercostal arteries (which can lose up to 50 mL of blood per minute), and other intrathoracic vessels. The location of these injuries makes controlling the bleeding impossible in the prehospital setting; in turn, the amount of circulating blood can be greatly reduced, causing hypovolemic shock. A hemothorax is a life-threatening injury that frequently requires the urgent placement of a chest tube and/or surgery.

A **massive hemothorax** is defined as accumulation of more than 1,500 mL of blood within the pleural space. For the average adult, this amount represents a nearly 25% to 30% blood volume loss, meaning that the patient's condition has progressed to decompensated shock. Because each lung can hold up to 3,000 mL of blood, it is possible for a patient to completely bleed out into the thoracic cavity.

As blood accumulates, it causes lung collapse. The degree of respiratory insufficiency depends on the amount of blood in the pleural space. Hypoxia results from the decreased gas exchange, and hypotension and inadequate perfusion may result from the blood loss. Hypoxia and hypovolemic shock develop rapidly.

Signs and symptoms of a massive hemothorax are produced by hypovolemia and respiratory compromise. You should suspect a hemothorax if the patient has signs and symptoms of shock or decreased breath sounds on the affected side—an indication that the lung is being compressed by the blood. Expect to find tachypnea; tachycardia; dyspnea; respiratory distress; hypotension; a narrowed pulse pressure; pleuritic chest pain; pale, cool, moist skin; dullness on percussion; and decreased or unequal breath sounds. Neck veins will be flat with associated hypovolemia or distended if there is increased intrathoracic pressure.

A **hemopneumothorax** is a pneumothorax with air and bleeding in the pleural space. Findings and management are the same as those for a hemothorax.

Managing the ABCs is the key consideration for patients with hemothorax. Administer oxygen and provide positive-pressure ventilation as needed. If hypovolemia is present, then give a fluid bolus, while using caution so as not to increase blood pressure past the point of maintaining perfusion and further increase bleeding. Provide rapid transport.

Pulmonary Contusion

In addition to fracturing ribs, any severe blunt trauma to the chest can injure the lung, resulting in pulmonary contusion, or bruising of the lung parenchyma. The pulmonary alveoli may become filled with blood in such a case, and fluid may accumulate in the injured area, leaving the patient hypoxic. Lung compliance is also decreased with such injuries. Pulmonary contusion is the most common injury from blunt thoracic trauma, and it is commonly associated with a rib fracture.

Severe pulmonary contusion should always be suspected in patients with a flail chest and usually develops over a period of hours. The damage in such a case may be diffuse or localized. Bruising of the lung parenchyma may also occur with high-energy shock waves from an explosion, high-velocity

missile wounds, wounds from low-velocity weapons, and rapid deceleration. Pulmonary contusions are often missed because of the high incidence of other associated injuries. To ensure you recognize them, you must maintain a high index of suspicion based on the MOI.

Although pulmonary contusion is usually caused by blunt trauma, it may also occur in scenarios involving explosions or events that create shock waves. There are three physical mechanisms for creating pulmonary contusions. The first is the implosion effect. With this mechanism, overexpansion of air in the lungs secondary to a pressure wave causes blunt trauma and results in rapid, excessive stretching and tearing of the alveoli. The second mechanism, the inertial effect, strips the alveoli from the heavier bronchial structures when the alveoli are pulled at varying rates by a pressure wave. The final mechanism is the Spalling effect, in which the liquid–gas interface, or exchange, is disrupted by a shock wave. The wave releases energy, and this differential transmission of energy causes disruption of the tissues.

Alveolar and capillary damage resulting from any of these mechanisms cause interstitial and intra-alveolar hemorrhage. It immediately leads to a loss of fluid and blood into the involved tissues, followed by white blood cell migration into the area, and, eventually, local tissue edema. This inflammation and local tissue injury and edema dilute the local surfactant in the alveoli, diminishing their compliance and causing alveolar collapse (atelectasis). Edema also reduces the delivery of oxygen across the capillary–alveolar interface, resulting in hypoxia. The hypoxia then worsens the situation by thickening the mucus produced, which may in turn lead to bronchiolar obstruction, air trapping, or an increase in physiologic dead air space and further atelectasis.

If the contusion is large, then the body attempts to compensate for its effects by vasoconstricting pulmonary blood flow and increasing cardiac output. Specifically, the body attempts to shunt blood from the injured area and increase its delivery to pulmonary tissue to oxygenate the blood. This pulmonary shunting decreases the functional reserve capacity and leads to mixed venous blood being returned to the heart, further worsening the hypoxemia.

Hypoxia and carbon dioxide retention lead to respiratory distress, dyspnea, tachypnea, agitation,

and restlessness. Because of the capillary injury and the hemorrhage into the pulmonary parenchyma, the patient may present with hemoptysis (coughing up blood). Evidence of overlying injury may include contusions, tenderness, crepitus, or paradoxical motion. Auscultation may reveal wheezes, rhonchi, crackles (formally known as rales), or diminished breath sounds in the affected area. In severe cases, cyanosis and low oxygen saturation levels may be found. The degree of respiratory compromise is directly related to the size of the area of contusion.

Treatment for pulmonary contusion is supportive. When managing a pulmonary contusion, both high-concentration oxygen and positive-pressure ventilation may be used to overcome the pathologic changes described earlier. Do not overhydrate the patient, as this will increase any pulmonary edema and bleeding. Give only small amounts of IV fluid to improve cardiac output as needed, titrating to a systolic blood pressure of 80 to 90 mm Hg.

Cardiac Tamponade

In cardiac tamponade, also known as pericardial tamponade, blood or other fluid collects in the **pericardium**, the fibrous sac surrounding the heart (**FIGURE 31-15**). In the context of chronic medical conditions, that fluid buildup occurs over time, and can be tolerated to a degree. In the context of acute trauma, that fluid is almost always blood and accumulates rapidly. This prevents the heart from filling

during the diastolic phase, causing a decrease in the amount of blood pumped to the body and lowering the blood pressure. Ultimately, as blood accumulates within the pericardial sac, it compresses the heart until it can no longer function and cardiac arrest occurs. Cardiac tamponade is relatively uncommon and is seen more often with penetrating injuries to the heart itself than with blunt injuries to the chest.

The pericardium attaches to the great vessels at the base of the heart. There are two layers: the visceral pericardium, which forms the epicardium, and the parietal pericardium, which is regarded as the sac itself. The purpose of the pericardium is to anchor the heart, restricting excess movement and preventing kinking of the great vessels. The space between the layers can normally hold 30 to 50 mL of fluid and can slowly distend with as much as 1,000 to 1,500 mL of blood or other fluid.

Accumulation of fluid over minutes to hours leads to increases in intrapericardial pressure. The more pliable structures within the pericardium—namely, the atria and the venae cavae—become compressed, which drastically reduces the preload being delivered to the heart and thereby diminishes stroke volume. The heart initially attempts to compensate for this reduction in preload by increasing the heart rate; however, this attempt to maintain cardiac output is only temporary because the continued bleeding will further restrict preload and diastolic filling. The pressure within the pericardial

FIGURE 31-15 Cardiac tamponade is a potentially fatal condition in which blood builds up within the pericardial sac, causing compression of the heart's chambers and dramatically impairing its ability to pump blood to the body.

sac will also reduce the perfusion in the myocardium, resulting in global myocardial dysfunction. The combination of these two processes leads to the development of hypotension. Fluid amounts as small as 50 mL can cause a reduction in cardiac output. Ischemic dysfunction may result in infarction. Removal of as little as 20 mL of blood may drastically improve cardiac output.

Cardiac tamponade can occur in both medical and trauma patients. In the medical setting, inflammatory processes (ie, pericarditis, uremia, myocardial infarction) lead to the slow collection of fluid within the pericardial sac and the gradual distention of the parietal pericardium. Conversely, the bleeding in the trauma patient is rapid, with blood loss from the coronary vasculature or the myocardium quickly collecting between the visceral and parietal pericardium.

The reduced cardiac output, hypoperfusion, and hypotension observed in cardiac tamponade produce the findings typical of a patient in shock: weak or absent peripheral pulses, diaphoresis, dyspnea, cyanosis, altered mental status, tachycardia, tachypnea, and agitation. Although these

symptoms alone do not suggest or exclude the presence of cardiac tamponade, identifying them can flesh out the physical assessment. The classic signs of cardiac tamponade, known as the Beck triad (narrowing pulse pressure, JVD, and muffled heart tones), occur only in the advanced stage. As noted earlier, heart tones can be difficult to auscultate in the often noisy prehospital setting or ambulance.

Physical findings in a patient with cardiac tamponade are not significantly different than those of a tension pneumothorax—namely, hypotension, JVD, tachycardia, altered mental status, and signs of tissue hypoperfusion. One way to differentiate between the two is to remember in cardiac tamponade, the breath sounds will be equal and the trachea will be midline because the lungs are not affected. **TABLE 31-2** compares the physical findings of these two emergencies.

In the patient with cardiac tamponade, it is essential to assess and manage the ABCs, administering oxygen and positive-pressure ventilation as needed. Inspect the chest and cover any open wounds with an occlusive dressing. Initiate large-bore IV access and provide a rapid fluid bolus

YOU are the Provider

Part 4

Your partner arrives with the spinal immobilization equipment. During your primary survey, you do not visualize any additional injuries. You secure your patient to the backboard, administer 100% oxygen via a nonrebreathing mask, and, with the assistance of track personnel, carry the patient approximately 1,000 feet (30 m) to your ambulance. On the basis of the patient's MOI and visible injuries, you elect to establish an 18-gauge IV line at a to-keep-open (TKO) rate given his blood pressure. You decide to provide rapid transport to the Level I trauma center instead of the community hospital based on the patient's injuries. Once en route, you contact the trauma center personnel and advise them of your estimated time of arrival. You establish a second 18-gauge IV line en route and set the line to a TKO rate. On arrival, you give your report to the trauma department staff and prepare your ambulance for the next call.

Recording Time: 15 Minutes

Respirations	30 breaths/min, shallow
Pulse	Strong and regular, 136 beats/min
Skin	Warm and dry
Blood pressure	104/62 mm Hg
Oxygen saturation (SpO₂)	97% on 100% oxygen
Pupils	PERRLA

7. Would this patient meet trauma system activation and/or criteria?
8. What are some possible interventions that may be required if the patient's condition deteriorates en route to the trauma center?

TABLE 31-2 Physical Findings of Cardiac Tamponade Versus Tension Pneumothorax

Physical Finding	Cardiac Tamponade	Tension Pneumothorax
Presenting sign/symptom	Shock	Respiratory distress
Neck veins	Distended	Distended
Trachea	Midline	Deviated (late sign)
Breath sounds	Equal on both sides	Decreased or absent on side of injury
Chest percussion	Normal	Hyperresonant on side of injury
Heart sounds	Muffled	Typically, normal

© Jones & Bartlett Learning.

to maintain systolic blood pressure at 80 to 90 mm Hg. Administering IV fluids may slow the patient's deterioration by momentarily increasing preload. Provide rapid transport and call for paramedic backup for treatment of potential dysrhythmias.

The ultimate treatment for cardiac tamponade is **pericardiocentesis**, which involves inserting a needle attached to a syringe far enough into the chest to penetrate the pericardium to withdraw fluid.

Myocardial Contusion

Myocardial contusion, or bruising of the heart muscle, may occur from blunt trauma. Blunt myocardial injury results in hemorrhage with edema and fragmented myocardial fibers along with cellular injury. Vascular damage may occur, and there may be a lacerated epicardium or endocardium. The fibrinous reaction at the contusion site may lead to delayed rupture or a ventricular aneurysm. The areas of damage are well demarcated, and conduction defects may occur resulting in cardiac dysrhythmias. Right- or left-side heart failure may also be present. See Chapter 18, *Cardiovascular Emergencies*, for a review of heart failure.

As an AEMT, you must maintain a high index of suspicion for serious injury in all patients with blunt chest trauma. Clinical signs of myocardial

contusion will vary based on the area of injury. Affected areas may include the vessels, the myocardium, or the conduction system. Associated injuries include one to three rib fractures and/or a sternal fracture. The patient may also present with sharp, retrosternal chest pain. The patient may or may not show external signs, such as bruising. Inspect the area to identify any soft-tissue or bone injury. Crackles (due to pulmonary edema from left ventricular dysfunction) may be heard on auscultation. Often, the pulse rate is irregular, but life-threatening dysrhythmias such as ventricular tachycardia and ventricular fibrillation are less common.

When you are treating a patient for a myocardial contusion, stay alert for signs of heart failure and beware of the risks of administering too much fluid if these signs appear. Provide supportive care including administering oxygen, frequently assessing vital signs, and establishing IV access. Assess for JVD and pulmonary edema. Call for paramedic backup early, and carefully monitor for rapid deterioration if the patient presents with tachycardia or an irregular pulse.

Myocardial Rupture

Myocardial rupture is an acute perforation of the ventricles, atria, intraventricular septum, intra-atrial septum, chordae tendineae, papillary muscles, or valves. Severe blunt force to the chest compresses the heart between the sternum and the vertebrae, which can rupture the myocardium. In penetrating trauma, a foreign object or bony fragment may be propelled into the heart, resulting in a laceration of the myocardial wall. Whether it occurs from a penetrating injury or blunt trauma, a ruptured myocardium is a life-threatening event.

Patients with myocardial rupture may present with acute pulmonary edema or signs of cardiac tamponade. They should receive supportive care and be rapidly transported to a facility where a thoracotomy can be performed.

Traumatic Aortic Disruption

Rupture of the aorta (also called **traumatic aortic disruption**) and aortic dissection occur most often in blunt trauma patients as a result of MVCs and falls. Aortic rupture occurs when an aortic aneurysm (an outpouching of the aorta where the vessel's diameter exceeds 2 inches [5 cm]) bursts, causing

massive blood loss.¹⁵ Aortic dissection, by comparison, involves a tear in the aortic intima and the formation of a false channel in the aorta; the diversion of blood into this false channel results in poor perfusion to the organs and tissues normally supplied with blood from this source.¹⁵ Of patients with an aortic *rupture*, only 60% survive until they arrive at the hospital; that is, 40% die in the prehospital stage.¹⁶ Notably, fewer than one-third of patients with either type of traumatic aortic disruption survive 3 days or longer.¹⁶ Given the body's entire blood volume passes through the aorta or great vessel, the high mortality associated with such an injury comes as no surprise. Nevertheless, some patients reached by EMS personnel can survive with prompt management, including surgical intervention.

The most widely accepted theory of how aortic dissection evolves holds that the aorta is injured at its fixed points due to shearing forces. The high-velocity, high-energy impacts that result in these injuries cause the aortic arch to swing forward. The resulting tension, along with rotation and torque on the area, causes the descending aorta to rupture at its point of attachment to the posterior thoracic wall (**FIGURE 31-16**).

As shown in Figure 31-16, the aorta includes three layers—the intima, the media, and the adventitia. If the injury tears the intima, then the high pressure within the aorta allows the blood to dissect

along the media. More severe injuries damage all three layers of the aorta, allowing blood to leak from the aorta into the surrounding tissues. If these tissues cannot stop the bleeding, then the patient can survive only with prompt intervention; otherwise, the injury will be rapidly fatal.

Recognizing a traumatic aortic disruption often comes from a high index of suspicion based on the MOI because a high percentage of patients have no signs of external chest trauma. Assessment findings associated with traumatic aortic disruption include retrosternal or interscapular pain described as “tearing,” dyspnea, dysphagia, hoarseness or stridor, ischemic pain of the extremities, and upper extremity hypertension with absent or decreased strength of femoral pulses. Hypotension and signs of shock may present as bleeding continues.

Medical care of patients with dissection or rupture of the aorta includes completing a primary survey, maintaining the ABCs, and providing immediate transport. The patient should receive gradual IV hydration en route to treat the hypotension. Aggressive fluid administration may result in sudden changes in the intra-aortic pressure that could worsen the injury. Expedited transport to a trauma center is essential.

Penetrating Wounds of the Great Vessels

Injuries to the great vessels usually are associated with injuries to the chest, abdomen, or neck. The chest contains several large blood vessels: the superior vena cava; the inferior vena cava; the pulmonary arteries; four main pulmonary veins; and the aorta, with its major branches distributing blood throughout the body. The abdominal aorta and inferior vena cava travel through the abdomen, and the carotid arteries and external jugular veins are located in the neck. Wounds to any of these vessels may be accompanied by massive hemorrhage, hypovolemic shock, cardiac tamponade, and enlarging hematomas. Frequently, blood loss is not obvious because it remains within the chest cavity. Hematomas may cause compression of any structure, including the venae cavae, trachea, esophagus, great vessels, or heart. Here, particularly, immediate transport to the hospital is critical—a few minutes can mean the difference between life and death.

FIGURE 31-16 Tension from a rapid deceleration injury can cause the descending aorta to rupture at its point of attachment to the posterior thoracic wall.

The management of potential injuries to the great vessels includes maintaining ABCs. Establish an IV line to provide hydration en route to the trauma center. Consider air transport if transport to a Level I trauma center may be delayed due to distance.

Diaphragmatic Injury

Injuries to the diaphragm may be the result of blunt or penetrating trauma. Because the diaphragm is protected by the liver on the right side, most diaphragmatic injuries (particularly those due to blunt trauma) occur on the left side. Once the diaphragm has been injured, the healing process is inhibited by the natural pressure differences between the abdominal and thoracic cavities.

Diaphragmatic injury may be life threatening; in studies, the overall mortality for such injuries has varied widely depending on the extent of injury and treatment.¹⁷ Injury occurs as high-pressure compression to the abdomen results in an increase in intra-abdominal pressure. Bowel obstruction and strangulation may also occur. As the diaphragm impinges on the thoracic cage, lung expansion is restricted, causing hypoventilation and hypoxia. A mediastinal shift can result in cardiac and respiratory compromise.

Injury to the diaphragm and the associated physical findings have been separated into three phases: acute, latent, and obstructive. The acute phase begins at the time of injury and ends with recovery from other injuries, which may overshadow the diaphragmatic injury, and serves to explain why more than two-thirds of these injuries are missed at the time of hospital admission.¹⁸ In the latent phase, the patient experiences intermittent abdominal pain due to the periodic herniation or entrapment of abdominal contents in the defect. The obstructive phase occurs when any abdominal contents herniate through the defect, cutting off their blood supply (infarct) in the process.

A rare but ultimate complication of a diaphragmatic injury is the herniation, or movement, of sufficient abdominal contents into the thoracic cavity. The resulting increased intrathoracic pressure both compresses the lung on the affected side and compromises circulatory function; this finding is called a tension gastrothorax.¹⁹

Signs and symptoms of diaphragmatic injury may be subtle. Findings include tachypnea,

tachycardia, respiratory distress, dullness to percussion, scaphoid (hollow, boat-shaped) abdomen, bowel sounds in the affected hemithorax, and decreased breath sounds.

Little can be done in the prehospital environment for diaphragmatic injury. Elevate the head of the backboard or stretcher if possible to help keep abdominal contents in the abdominal cavity, and provide positive-pressure ventilation for hypoventilation.

Words of Wisdom

Avoid using nitrous oxide in patients with a possible diaphragmatic injury because it can greatly increase the volume of gas within entrapped viscera.

Esophageal Injury

Penetrating trauma is the most frequent cause of esophageal injury. It is rare in blunt trauma, but could potentially be life threatening if undetected. Missile and knife wounds may penetrate the esophagus, or it may perforate spontaneously in violent emesis, carcinoma (cancer), or anatomic distortions produced by diverticula or gastric reflux. Damage to the esophagus is often associated with other significant injuries because of its location in the body.

Patients typically present with pain (eg, pleuritic chest pain or pain made worse by swallowing), hoarseness, dysphagia, respiratory distress, and shock. Signs of cervical esophageal perforation include local tenderness and subcutaneous emphysema. In nontraumatic causes, you may be able to detect resistance of the neck on passive motion. Such an exam is contraindicated in trauma patients. If the perforation is in the intrathoracic esophagus, then signs may include mediastinal emphysema, mediastinitis, subcutaneous emphysema (suspect associated tracheal injury), mediastinal crunch, and splinting of the chest wall.

Prehospital care for a patient with esophageal injury is supportive. Manage the patient's symptoms.

Tracheobronchial Injury

Tracheobronchial injury is rare, occurring in fewer than 3% of chest trauma cases.²⁰ When it occurs, it is usually the result of blunt or penetrating trauma and carries a high mortality rate.

As with aortic injuries, the site of a tracheobronchial injury is often close to a point of attachment: specifically, the carina. The injury to the trachea or main stem bronchi allows for rapid movement of air into the pleural space, resulting in a pneumothorax. As this injury progresses to a tension pneumothorax, a needle thoracentesis is often insufficient because the rate of air entry into the pleural space exceeds the rate at which the air can escape from the inserted angiocatheter. Such injury also causes severe hypoxia.

Findings associated with tracheobronchial injury include hoarseness, tachypnea, tachycardia, massive subcutaneous emphysema, dyspnea, respiratory distress, hemoptysis, and signs of tension pneumothorax that do not respond to needle decompression.

Early recognition and rapid transport are key to managing tracheobronchial injury. Treat the patient symptomatically, positioning appropriately and ventilating as needed. Because of the rapid loss of air into the pleural space, high ventilatory pressures should be avoided when you are providing positive-pressure ventilation (bag the patient gently and slowly).

Traumatic Asphyxia

Sometimes patients will experience a sudden, severe compression injury of the chest, which produces a rapid increase in intrathoracic pressure. This condition is called **traumatic asphyxia** (FIGURE 31-17). Traumatic asphyxia may occur in an unrestrained driver who hits a steering wheel or a pedestrian who is compressed between a vehicle and a wall. A sudden compressional force squeezes the chest, and blood backs up into the head and neck, causing the jugular veins to engorge and capillaries to rupture.

FIGURE 31-17 Traumatic asphyxia has a characteristic appearance.

© Charles Stewart MD, EMDM MPH.

The sudden increase in intrathoracic pressure results in the characteristic appearance of traumatic asphyxia, including distended neck veins; cyanosis in the face and upper neck, extremities, and the torso above the level of the compression; and swelling and cyanosis of the tongue and lips. Ocular hemorrhage may be mild, such as bleeding into the anterior surface of the eye (**subconjunctival hematoma**), or extremely dramatic, causing the eyes to protrude from their normal position (**exophthalmos**). The skin below the area of compression remains normal color, and hypotension occurs when the pressure is released.

Again, early recognition and rapid transport are key. Treat the patient's symptoms, position the patient appropriately, and ventilate as needed. Take cervical spine precautions, including spinal immobilization. Obtain IV access with two large-bore IV lines. Transport the patient to the nearest appropriate trauma center.

YOU are the Provider SUMMARY**1. Should you immediately approach the patient? Is the scene safe?**

No, the scene is not safe, and you should not immediately approach the patient. Whenever your ambulance provides standby services at an event, it is always recommended to meet with the event representative, who will brief you on the positioning of the ambulance, access and egress routes, and any hand signals or visual clues that may direct you. The scene cannot be made safe until all motocross riders have stopped riding on the track. You should not enter the track until all riders have come to a stop and you are directed to enter by the event representative.

2. What are some possible injuries this patient could have?

Until proven otherwise, this patient has multisystem trauma and may present with a wide variety of injuries. You should expect both open and closed fractures, arterial bleeding, hemothorax, pneumothorax, and hemodynamic instability.

3. Does this patient require spinal immobilization?

Initially, this patient requires, at a minimum, manual stabilization of the head. A complete and thorough history and physical exam, in conjunction with your local protocols, will further direct your actions.

4. Does this patient require helmet removal?

If you are able to adequately treat and immobilize the patient with his helmet in place, then it should remain on his head. However, if the helmet interferes with the ability to administer oxygen or ventilation or to otherwise manage the airway, or it interferes with your ability to properly secure the patient to a spinal immobilization device, it should be removed. In general, motocross helmets do not fit the head tight

enough to allow effective immobilization to occur while the patient is still wearing one. Helmet removal is described in Chapter 30, *Head and Spine Injuries*.

5. What are some possible causes of this patient's dyspnea?

This patient could possibly be experiencing a flail chest injury, hemothorax, pneumothorax, pulmonary contusion, myocardial contusion, cardiac tamponade, or possibly tracheobronchial disruption.

6. Does this patient require rapid transport to the hospital?

A blow significant enough to fracture the sternum causes severe hyperflexion of the thoracic cage. The patient's condition is critical. Myocardial and/or pulmonary contusion or myocardial rupture may occur with compression of the thorax. Therefore, rapid transport to the appropriate facility is critical.

7. Would this patient meet trauma system activation and/or criteria?

Typical trauma center criteria fall into one of three categories: anatomic, physiologic, and mechanism criteria. On the basis of these criteria, the patient would meet any Level I trauma center activation protocols. Trauma center criteria are discussed in detail in Chapter 26, *Trauma Overview*.

8. What are some possible interventions that may be required if the patient's condition deteriorates en route to the trauma center?

The patient may require positive-pressure ventilations with a bag-mask device, increased fluid boluses, and CPR. Paramedic interventions may include endotracheal intubation and needle chest decompression.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 07-07-21	Incident No.: 20093913671	Nature of Call: Traumatic injury	Location: Glendale Motorsports		
Dispatched: —	En Route: —	At Scene: 1420	Transport: 1432	At Hospital: 1450	In Service: 1515

Patient Information

Age: 24
Sex: M
Weight (in kg [lb]): 82 kg (180 lb)

Allergies: No known drug allergies
Medications: None
Past Medical History: Multiple broken bones from extreme sports
Chief Complaint: Blunt chest trauma

Vital Signs

Time: 1425	BP: 98/55	Pulse: 120	Respirations: 32	Spo₂: 97%
Time: 1435	BP: 104/62	Pulse: 136	Respirations: 30	Spo₂: 97%

EMS Treatment (circle all that apply)

Oxygen @ 15 L/min via (circle one): NC (NRM) Bag-mask device		Assisted Ventilation	Airway Adjunct	CPR:
Defibrillation	Bleeding Control	Bandaging	Splinting	Other: Spinal immobilization; established two 18-gauge IV lines

Narrative

EMS at Glendale Motorsports for motocross race. Witnessed rider in full protective gear (helmet, knee/elbow pads, and chest protector) launch from jump approximately 15 feet in the air and land on his front tire, going headfirst over handlebars, hitting the ground in a left lateral position, ultimately coming to rest in the supine position. As we were waiting for the track official to stop the race, we witnessed another rider making the same jump, come down, and directly hit the first patient's chest. When we were directed onto the track to the patient, he presents AO×4, with a patent airway. Breathing appears labored. Manual stabilization obtained. He is able to recall all events, and states his chest hurts and it is hard to breathe. Shirt and chest protector removed, pain and tenderness noted midsternum, possible crepitus. Patient denies having any head or neck pain. Helmet removed to facilitate immobilization to backboard. Patient secured to board with pulse, motor, sensation present before and after. 100% O₂ applied via a nonrebreathing mask. Bilateral 18-gauge IV lines established both at TKO rate. Patient transported emergent to Altru Hospital with trauma activation requested en route. On arrival, care and report given to ED staff without incident. **Note: Kittson County Hospital was bypassed in lieu of Altru because of the patient meeting trauma protocols.

End of report

Prep Kit

Ready for Review

- The thoracic cavity extends from the lower end of the neck to the diaphragm, but an injury to the chest may also injure structures in the abdomen. Always assume there are both chest and abdominal injuries when managing a patient who has sustained a chest injury.
- The thorax contains many important structures, such as the trachea and great vessels, and organs, such as the heart and lungs; therefore, chest injuries can have serious consequences, such as adverse effects on the body's ability to perform respiration and ventilation. Respiratory alkalosis and respiratory acidosis can result.
- A blow to the chest (blunt trauma) may fracture the ribs, the sternum, or whole areas of the chest wall. Compression of these structures creates other problems, including contusions of the lungs and the heart and possible damage to the aorta. Even if the skin and chest wall are intact, the contents of the thorax may be injured.
- Thoracic trauma may impair cardiac output, decreasing blood pressure and perfusion to vital organs. Bleeding into the thoracic cavity significantly increases the chance of hypovolemia and hypoxia. Significant blood loss can disrupt critical processes.
- A patient with severe chest pain tends to have shallow breathing. This further reduces minute volume—the volume of air exchanged between the lungs and environment in 1 minute. If blood collects in the thoracic cavity, then this can also prevent full expansion of the lungs.
- There are two types of chest injuries: penetrating (open) injuries and blunt (closed) injuries. Specific chest injuries can include rib fractures, flail chest, sternal fracture, clavicle fracture, commotio cordis, simple pneumothorax, open pneumothorax, tension pneumothorax, hemothorax, hemopneumothorax, pulmonary contusion, cardiac tamponade, myocardial contusion, myocardial rupture, traumatic aortic disruption, penetrating wounds of the great vessels, diaphragmatic injury, esophageal injury, tracheobronchial injury, and traumatic asphyxia.
- Signs and symptoms of chest injury include pain at the site of injury or localized pain that worsens with breathing; bruising to the chest wall; crepitus; penetrating injury to the chest; dyspnea; hemoptysis; failure of one or both sides of the chest to expand normally with inspiration; rapid, weak pulse; low blood pressure; and cyanosis around the lips or fingernail beds.
- Note whether heart sounds are easily heard or muffled on auscultation. Muffled heart sounds are an important clue when distinguishing tension pneumothorax and cardiac tamponade.
- JVD suggests increased IV pressure that can occur with a tension pneumothorax or cardiac tamponade. Note that JVD must be measured with the patient in a 45° semi-Fowler position.
- If the patient's mental status permits, then ask about a history of dyspnea, chest pain, other areas of pain or discomfort, symptoms before the incident, history of cardiorespiratory disease, any medications the patient may be taking, and, in a motor vehicle collision, whether restraints were used.
- Monitoring a patient's ABCs is the primary management for all patients; this is no different for the patient with thoracic injury. Occlude open chest wounds with an occlusive dressing. Stabilize any flail segments. Administer positive-pressure ventilation, if indicated. Consider definitive airway management. Maintain circulation and gain IV access. Finally, call for additional backup if needed and provide rapid transport.
- IV fluid therapy during thoracic trauma should be closely monitored and administered according to local protocol. The goal is to maintain adequate perfusion without causing a marked increase in blood pressure.
- Any injury to the thoracic cavity may disrupt normal cardiac function. Always treat the

patient based on advanced cardiac life support and local protocols. Consider aggressive airway management.

- Multiple rib fractures, with or without a fracture of the sternum, often result in flail chest, in which a portion of the chest wall is detached from the thoracic cage and moves paradoxically during respiration.
- Flail chest causes painful breathing and requires respiratory support and supplemental high-flow oxygen. External stabilization of a flail chest is not indicated. Positive-pressure ventilation may be necessary in severe cases with resultant inadequate ventilator function.
- If a sternal fracture is present, then you should expect to find pain and tenderness over the sternum, and crepitus on palpation.
- If a clavicle fracture is present, then you should splint it with a sling and swathe. Clavicle fracture can result in neurovascular compromise.
- Commotio cordis is cardiac arrest that results from a patient receiving a blow during the heart's repolarization period. Such a patient may present with ventricular fibrillation that responds positively to defibrillation provided within the first 3 minutes.
- Simple pneumothorax is the accumulation of air in the pleural space, occurring when air enters a hole in the chest wall or lung. The lung collapses as pressure builds in the pleural space. Cover open chest wounds with an occlusive dressing and manage the ABCs.
- Spontaneous pneumothorax can occur in people with weak areas on the surface of the lungs. The patient will experience sudden, sharp pain and shortness of breath without known cause. The most critical intervention is conducting repeated assessments to ensure the injury has not progressed to a tension pneumothorax.
- Open pneumothorax is a pneumothorax in which the pleural space is in direct contact with the atmosphere. The opening causes increased thoracic pressure and the lung collapses. Sucking sounds may be heard on inhalation; this is often called a sucking chest wound.
- Seal a sucking chest wound with an occlusive dressing. If the patient shows signs of a tension pneumothorax, then burp the dressing (raise one side of the dressing to allow air to escape).
- A tension pneumothorax can occur in a closed, blunt injury of the chest in which a fractured rib lacerates the surface of the lung or as a result of the paper bag syndrome. The classic signs of a tension pneumothorax are an absence of breath sounds on the affected side, unequal chest rise, tachycardia and dysrhythmias such as progression to ventricular tachycardia and ventricular fibrillation, JVD, narrow pulse pressure, and as a very late sign, tracheal deviation. In the event of a closed tension pneumothorax, consider calling for paramedic backup because needle chest decompression will need to be performed.
- Hemothorax is a life-threatening condition in which blood accumulates between the parietal and visceral pleura of the lung. Look for signs and symptoms of shock and decreased breath sounds on the affected side. Manage the ABCs, administer oxygen and positive-pressure ventilation as needed, give a fluid bolus if needed, and provide rapid transport.
- Pulmonary contusion is bruising of the lung and may occur in conjunction with fractured ribs. Treatment is supportive. Ensure you do not overhydrate the patient because this could create increased pulmonary edema and bleeding.
- Cardiac tamponade is collection of blood in the pericardium, which prevents the heart from pumping effectively. Signs and symptoms include weak or absent peripheral pulses, diaphoresis, dyspnea, cyanosis, altered mental status, tachycardia, tachypnea, and agitation; Beck triad (narrowing pulse pressure, JVD, and muffled heart sounds) occurs in the advanced state. Manage the ABCs, administer oxygen, and be cautious with positive-pressure ventilation because this may cause a tension pneumothorax. Provide a rapid fluid bolus to maintain cardiac output and ensure rapid transport.
- Myocardial contusion is bruising of the heart muscle, which can lead to heart failure.

Maintain a high suspicion for serious injury in patients who experience blunt chest trauma. Pulse may be irregular, but life-threatening dysrhythmias are uncommon. Limit fluids if signs of heart failure are present.

- Myocardial rupture is acute perforation of any portion of the heart. This life-threatening condition requires aggressive care of the ABCs and rapid transport.
- Traumatic aortic disruption is dissection or rupture of the aorta. Recognition often comes from a high index of suspicion based on the MOI. Assessment may reveal retrosternal or interscapular pain described as “tearing,” ischemic pain of the extremities, and hoarseness or stridor, among others. Management includes maintaining the ABCs and taking care not to overhydrate and increase bleeding.
- Laceration of the large blood vessels in the chest can cause a fatal hemorrhage. Suspect this condition in any patient with a chest wound who shows signs of shock, even if you see little blood; it may be collecting within the chest cavity. Provide immediate transport—a few minutes can be the difference between life and death.
- The diaphragm can be injured when the chest is injured, but signs and symptoms can be subtle. Findings include scaphoid abdomen, dullness to percussion, and (sometimes) bowel

sounds in the affected side of the thorax. Provide rapid transport.

- Esophageal injury, like many chest injuries, is a life-threatening condition. Signs may include local tenderness and subcutaneous emphysema. Provide rapid transport.
- Damage to the esophagus is often associated with other significant injuries because of its location in the body. Patients typically present with pain, hoarseness, dysphagia, respiratory distress, and shock. Prehospital care is supportive.
- Tracheobronchial injury is rare but can be a significant cause of mortality. An injury to the trachea or main stem bronchi allows for rapid movement of air into the pleural space, resulting in a pneumothorax. If this occurs, then the tension pneumothorax may not respond to needle chest decompression.
- Traumatic asphyxia occurs when a patient experiences sudden, severe compression injury to the chest, causing a rapid increase in intrathoracic pressure. This injury squeezes the chest, such that blood backs up into the head and neck, causing the appearance of distended neck veins; cyanosis in the face and upper part of the neck, extremities, and the torso above the level of the compression; swelling and cyanosis of the tongue and lips; bulging eyes; and swelling or hemorrhage of the conjunctiva. Skin below the area of compression remains normal color.

Vital Vocabulary

atelectasis A condition of airless or collapsed alveoli that causes pulmonary shunting, ventilation/perfusion mismatching, and possibly hypoxemia.

cardiac output The amount of blood pumped by the heart per minute.

cardiac tamponade Compression of the heart caused by a buildup of blood or other fluid in the pericardial sac.

chemoreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in chemical composition of the blood to help maintain homeostasis.

closed chest injury An injury to the chest in which the skin is not broken, usually from blunt trauma.

commotio cordis An event in which an often fatal cardiac dysrhythmia is produced by a sudden blow to the thoracic cavity.

crepitus The sensation felt when broken bone ends grind together.

exophthalmos Bulging of the eyes.

flail chest A condition in which two or more ribs are fractured in two or more places or in association with a fracture of the sternum, so a segment

of chest wall is effectively detached from the rest of the thoracic cage.

hemopneumothorax A collection of blood and air in the pleural cavity.

hemoptysis The spitting or coughing up of blood.

hemothorax A collection of blood in the pleural cavity.

jugular venous distention (JVD) A prominence of the jugular veins caused by increased volume or increased pressure within the central venous system or the thoracic cavity.

massive hemothorax An accumulation of more than 1,500 mL of blood within the pleural space.

mediastinum The space between the lungs, in the center of the chest, that contains the heart, trachea, large blood vessels, main stem bronchi, part of the esophagus, lymphatic channels, and paired vagus and phrenic nerves.

minute volume The amount of air moved in and out of the respiratory tract (minus the dead space) per minute; determined by the tidal volume multiplied by the respiratory rate. Also called minute ventilation.

myocardial contusion A bruise of the heart muscle.

myocardial rupture An acute perforation of the ventricles, atria, intraventricular septum, intra-atrial septum, chordae, papillary muscles, or valves.

occlusive dressing A dressing made of gauze with petroleum jelly, aluminum foil, or plastic that prevents air and liquids from entering or exiting a wound.

open chest injury An injury to the chest in which the chest wall itself is penetrated by some external object such as a knife or bullet.

open pneumothorax An accumulation of air or gas in the pleural space, resulting from a defect or penetration into the chest wall that allows air to enter the thoracic cavity.

paper bag syndrome Rupture of the lungs that occurs as the chest meets with blunt trauma after taking a deep breath, usually during a motor vehicle crash, similar to the rupture of an air-filled paper bag.

paradoxical motion The inward movement of the chest during inhalation and outward movement during exhalation; the opposite of normal chest wall movement during breathing; occurs in a flail chest.

pericardiocentesis The ultimate treatment for cardiac tamponade, which involves inserting a needle attached to a syringe far enough into the chest to penetrate the pericardium to withdraw fluid.

pericardium A thick, fibrous membrane that surrounds the heart; also called the pericardial sac.

pleural space The potential space between the visceral and parietal pleura of the lung and chest wall, respectively; it is normally absent, as these surfaces are usually in direct contact.

pneumothorax A partial or complete accumulation of air in the pleural space.

pulmonary contusion A bruise of the lung.

pulse pressure The difference between the systolic blood pressure and the diastolic blood pressure.

pulsus paradoxus A drop in the systolic blood pressure of 10 mm Hg or more; commonly seen in patients with cardiac tamponade or severe asthma.

spontaneous pneumothorax Pneumothorax that occurs when a weak area on the lung ruptures in the absence of major injury, allowing air to leak into the pleural space.

subconjunctival hematoma Bleeding into the anterior surface of the eye.

sucking chest wound An open or penetrating chest wall wound through which air passes during inspiration and expiration, creating a sucking sound.

tension pneumothorax An accumulation of air or gas in the pleural space that progressively collapses the lung with potentially fatal results.

traumatic aortic disruption Dissection or rupture of the aorta.

traumatic asphyxia A pattern of injuries seen after a severe force is applied to the thorax, forcing blood from the great vessels and back into the head and neck.

Chapter 32

Abdominal and Genitourinary Injuries

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Abdominal and Genitourinary Trauma

Recognition and management of

- Blunt versus penetrating mechanisms (p 1506)
- Evisceration (p 1509)
- Impaled object (p 1517)

Pathophysiology, assessment, and management of

- Solid and hollow organ injuries (pp 1503–1519)

- Blunt versus penetrating mechanisms (pp 1520–1521)
- Evisceration (pp 1523–1524)
- Injuries to the external genitalia (pp 1512–1513)
- Vaginal bleeding due to trauma (p 1526)
- Sexual assault (p 1526)
- Vascular injury (pp 1513–1514)
- Retroperitoneal injuries (pp 1505–1506)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the abdomen, including the abdominal quadrants and boundaries. (pp 1502–1503)
2. Discuss the difference between hollow and solid organs. (pp 1503–1504)
3. Review the anatomy and physiology of the female and male genitourinary systems. (pp 1504–1505)
4. Describe some special considerations related to the care of pediatric patients and geriatric patients who have experienced abdominal trauma. (p 1506)
5. Discuss closed abdominal injuries, providing examples of the mechanisms of injury that are likely to cause this type of trauma in a patient, as well as key signs and symptoms. (pp 1506–1508)
6. Discuss open abdominal injuries, including ways to distinguish low-velocity, medium-velocity, and high-velocity injuries; examples of the mechanisms of injury that would cause each; and signs and symptoms exhibited by a patient who has experienced this type of injury. (pp 1508–1509)

7. Describe the different ways hollow and solid organs of the abdomen can be injured and include the signs and symptoms a patient might exhibit, depending on the organ or organs involved. (pp 1505–1506)
8. Discuss the types of traumatic injuries that may be sustained by the organs of the male and female genitourinary systems, including the kidneys, urinary bladder, and internal and external genitalia. (pp 1509–1514)
9. Discuss the assessment of a patient who has experienced an abdominal or genitourinary injury. (pp 1514–1519)
10. Discuss special considerations related to patient privacy when assessing a patient with a genitourinary injury. (p 1514)
11. Discuss the emergency medical care of a patient who has sustained a closed abdominal injury. (pp 1520–1521)
12. Discuss the emergency medical care of a patient who has sustained an open abdominal injury, including penetrating injuries and abdominal evisceration. (pp 1521–1524)
13. Discuss the emergency medical care of a patient who has sustained a genitourinary injury related to the kidneys, bladder, external male genitalia, female genitalia, or rectum. (pp 1524–1526)

SKILLS OBJECTIVES

1. Demonstrate proper emergency medical care of a patient who has experienced a blunt abdominal injury. (p 1521)
2. Demonstrate proper emergency medical care of a patient who has a penetrating abdominal injury with an impaled object. (p 1522)
3. Demonstrate how to apply a dressing to an abdominal evisceration wound. (p 1524)

Introduction

The abdomen is the lower of the two major body cavities, extending from the diaphragm to the pelvis. It contains several organs that make up the digestive, urinary, and genitourinary systems. Although any of these organs may be injured, some are better protected than others. You must know where these organs are located within the abdominal and pelvic cavities. You must also understand their functions so that when an illness or injury occurs, you can assess its seriousness.

The abdomen contains multiple organs and organ systems that are not well protected, and it is a highly vascular region. Injuries to the abdomen that go unrecognized or untreated are a leading cause of traumatic death, particularly in pediatric patients.¹ Similarly, trauma to the genitourinary system is often overlooked, despite 10% of all trauma patients having some form of genitourinary injury.² Given this risk, a high index of suspicion and prompt treatment are required with any abdominal or genitourinary injury.

Anatomy and Physiology Review

Abdominal Quadrants

The abdomen is divided arbitrarily into quadrants by two perpendicular lines that intersect at the umbilicus (**FIGURE 32-1**). These areas are referred to as the right upper quadrant, left upper quadrant, right lower quadrant, and left lower quadrant. Remember that here, right and left refer to the patient's right and left, not yours. These quadrants provide a frame of reference for identifying and reporting abdominal signs and symptoms.

The quadrant location of bruising or pain can delineate which organs are possibly involved in a traumatic injury. Organs commonly found in the right upper quadrant are the liver, gallbladder, duodenum of the intestines, and a small portion of the pancreas. The stomach occupies most of the left upper quadrant, but shares this space with the spleen. The pancreas is mostly posterior to this region. Different portions of the intestines

are located in each of the four quadrants. The left lower quadrant holds some of the large and small bowel, notably the descending colon. The right lower quadrant also holds portions of the large and small intestines that include the ascending colon and the appendix, which can be a source of infection if it ruptures.

The diaphragm is the dividing line between the thoracic and abdominal cavities. Because the diaphragm moves its position during inspiration and expiration, in addition to other pulmonary and thoracic structures, it may be injured along with abdominal organs. For example, patients may take a deep breath as they see the traumatic force approaching, causing the diaphragm to flatten.

FIGURE 32-1 The abdomen is divided into four general quadrants.

© Jones & Bartlett Learning.

Hollow and Solid Organs

The abdomen contains both hollow and solid organs, any of which may be damaged. Owing to the size of the **peritoneal cavity** (the abdominal cavity) and the structures it includes, a patient could lose all circulating blood volume into this area without any visible external bleeding.

Hollow organs, including the stomach, gallbladder, intestines, ureters, and urinary bladder, are actually structures through which materials pass (**FIGURE 32-2**). Hollow organs usually contain food that is in the process of being digested, urine that is being passed to the bladder for release, or bile. They are more resilient to blunt trauma and less likely to be injured by trauma unless they are full.

FIGURE 32-2 The hollow organs in the abdominal cavity are structures through which materials pass.

YOU are the Provider

Part 1

As you and your partner are enjoying the nice day outside your station, your ambulance is dispatched to an "ATV [all-terrain vehicle] accident, unknown further" call. As you are responding, dispatch informs you that the patient is a 32-year-old woman who hit a rock at moderate speed and possibly has a tree branch impaled in her abdomen.

1. Do you need additional resources to manage this call?
2. What are the potential injuries you may encounter?

FIGURE 32-3 The solid organs are solid, highly vascular masses of tissue that do much of the chemical work in the body; for example, digestion, excretion, and energy production.

© Jones & Bartlett Learning.

The **solid organs**, as their name suggests, are solid masses of tissue. They include the liver, spleen, pancreas, and kidneys (**FIGURE 32-3**). The kidneys and great vessels (the abdominal aorta and the inferior vena cava), as well as most of the pancreas, lie in the retroperitoneal space, directly behind the peritoneal cavity (**FIGURE 32-4**). Solid organs have a rich blood supply, so their injury can cause severe hemorrhage. Blood in the peritoneal cavity irritates tissue and fills any voids or spaces, which can make it difficult to determine the exact source of the bleeding. Unlike gastric juices and bacteria, blood within the peritoneal cavity does not provoke an inflammatory response. Therefore, the absence of pain and tenderness does not necessarily mean the absence of major bleeding in the abdomen. Abdominal pain from penetration or rupture of solid organs has a slow onset.

The Genitourinary System

The genitourinary system is composed of the reproductive system and the urinary system. The urinary system controls the discharge of certain waste materials filtered from the blood by the kidneys. In the urinary system, the kidneys are solid organs; the ureters, bladder, and urethra are hollow organs.

The reproductive system controls the reproductive processes from which life is created.

FIGURE 32-4 Different organs of the abdomen are contained in the peritoneum (**A**), the retroperitoneal space (**B**), and the pelvis (**C**).

© Jones & Bartlett Learning.

The male genitalia, except for the prostate gland and the seminal vesicles, lie outside the pelvic cavity. The female genitalia, except for the vulva, clitoris, and labia, are contained entirely within the pelvis. In females, conditions in the reproductive system may cause abdominal pain. Such emergencies are discussed in Chapter 25, *Gynecologic Emergencies*. Refer to Chapter 7, *The Human Body*, for more information about the anatomy and physiology of the urinary and reproductive systems.

Pathophysiology

Abdominal injuries may be as obvious as loops of intestines protruding from a stab wound or as subtle as a laceration to the liver or spleen due to blunt trauma. Injuries to the abdomen are considered open or closed and can involve hollow and/or solid organs.

General Pathophysiologic Concerns

Hemorrhage

Hemorrhage is a major concern in patients with abdominal trauma. It can occur when there is external or internal blood loss. When you are caring for patients with abdominal trauma, especially blunt abdominal trauma, estimating the volume of blood lost is difficult. Signs and symptoms will vary greatly depending on the volume of blood lost and the rate at which the body is losing blood. Key indicators of hemorrhagic shock will become apparent with the assessment of the neurologic and cardiovascular systems.

As hypovolemia increases, the patient will initially experience agitation and confusion. The heart compensates early for this loss by an increase in heart rate (tachycardia) and stroke volume. As hypoperfusion continues, arterial blood flow

throughout the body becomes insufficient to meet the increased demands of the tissues in every organ system. If left untreated, hypoperfusion will result in anaerobic metabolism and acidosis.

Peritonitis and Pneumoperitoneum

Injuries to hollow or solid organs can result in the spillage of their contents into the abdominal cavity. When the enzymes, acids, or bacteria leak from hollow organs into the peritoneal or retroperitoneal space, they cause irritation of the nerve endings. These nerve endings are found in the fascia of the surrounding tissues. As the inflammation affects deeper nerve endings (such as the endings of the afferent nerves), localized pain will result. Pain is localized if the extent of the contamination is confined; pain becomes generalized if the entire peritoneal cavity is involved.

If ruptured or lacerated organs spill their toxic contents into the peritoneal cavity, the result may be an intense, potentially life-threatening inflammatory reaction called **peritonitis**. The first signs of peritonitis are severe abdominal pain, tenderness, and muscular spasm. Later, normal bowel sounds diminish or disappear as the bowel stops functioning. A patient may feel nauseated and may vomit; the abdomen may become distended and firm to the touch. If the site of the perforation or rupture is not rapidly identified and repaired, severe infection and septic shock may develop. Patients with peritonitis generally prefer to lie very still with their legs drawn up because it hurts to move or straighten their legs. They may complain about every bump in the road during transport.

Pneumoperitoneum, or free air in the peritoneal cavity, may also occur as a result of rupture of

Words of Wisdom

A patient may lose all circulating blood volume internally without any visible external hemorrhage. You must maintain a high index of suspicion based on the mechanism of injury (MOI) and changes in vital signs. Tachycardia is a common sign of blood loss, whether the loss is internal or external.

Special Populations

Falls are the most common MOI in geriatric patients.^{3,4} In addition to the typical orthopaedic injuries that a geriatric patient sustains in a fall, the abdominal organs that have lost some elasticity over time are exposed to forces that can damage them. Specifically, the aorta, liver, and spleen are at risk of injury from falls. In addition, a geriatric patient's brittle bones can fracture in a fall, creating dangerously sharp edges that can puncture internal organs.

FIGURE 32-5 Blunt trauma to the abdomen can occur when a patient strikes the steering wheel of an automobile as a result of a crash.

© American Academy of Orthopaedic Surgeons.

a hollow organ, perforated peptic ulcer, recent abdominal surgery, or rupture of an abscess, among other conditions. Perforation with free air is usually very painful. Any air in the peritoneal cavity seeks the most superior space or void; thus, the location of the air can change with positioning of the patient. Pneumoperitoneum secondary to hollow organ rupture requires surgical intervention.

Closed Abdominal Injuries

A **closed abdominal injury** is one in which a severe blow damages the abdomen without breaking the skin; closed abdominal injuries are also known as blunt injuries. Such a blow might come from the patient striking the handlebar of a bicycle or the steering wheel of a car (**FIGURE 32-5**). Other causes of closed injuries include compression, deceleration, crush injuries, motorcycle crashes, falls, assaults, blast injuries, and pedestrian injuries.

Words of Wisdom

When considering fluid administration for a patient with the potential for internal bleeding, it is important not to overhydrate. The goal is to maintain a systolic blood pressure of 80 to 90 mm Hg to allow for perfusion but not increase bleeding. The presence of a radial pulse has been used as a proxy for a systolic blood pressure greater than 80 mm Hg, although this relationship is not well supported by scientific evidence. If systolic blood pressure is greater than 80 mm Hg, set the intravenous (IV) flow at a to-keep-open (TKO) rate to avoid exacerbating any internal bleeding.

Compression injuries are typically caused by a poorly placed lap belt. A compression injury can also be caused when a person is run over or rolled over by vehicles or objects. These compression forces will deform hollow organs, increasing the pressure within the abdominal cavity. This dramatic change in abdominal pressure can cause a rupture of the small intestine or diaphragm. Deceleration injuries commonly occur when a person or the vehicle in which the person is traveling strikes a large immovable mass such as a larger vehicle, a bridge abutment, or the ground.

Special Populations

In pediatric patients, a common MOI is a motor vehicle-versus-pedestrian or motor vehicle-versus-bicycle crash. In pediatric patients, the chest and abdomen are less protected by bony structures than in adults. A pediatric patient may experience significant transfer of energy on impact. In pediatric patients, the rib cage is so flexible that the chest can be flattened almost to the spine before rib fractures occur. This extensive compression can involve not only the organs of the chest, but also the organs in the abdomen. The ribs then recoil to their normal position, and the patient is left with few outward signs that an injury has occurred.

Crush injuries are the result of external factors at the time of impact; they differ from deceleration injuries, which occur before impact. When abdominal contents are compressed between the anterior abdominal wall and the spinal column (or other structures in the rear), crushing occurs. Solid organs like the kidneys, liver, and spleen are at the greatest risk of injury from this mechanism. Direct application of crushing forces to the abdomen would come from objects like the dashboard, the front hood of a car (in a vehicle-pedestrian crash), or from falling objects. Additionally, these injuries can be caused by a restraining device that has not been properly attached or worn or by the steering wheel striking the abdominal cavity of an unrestrained driver as the person is propelled forward.

Many organs in the abdominal cavity may be injured from blunt trauma. The diaphragm, along with the abdominal wall, may sustain compression tears. The solid organs (eg, the liver and spleen)

may burst, causing severe bleeding, and the hollow organs (eg, the gallbladder and intestines) may rupture on impact, spilling their contents into the abdominal cavity. Shearing may cause tears from the ligamentum teres hepatis, which extends from the liver, or an avulsion of the liver from the inferior vena cava at the hepatic veins. There may be an avulsion of the pedicle, or stem, of the spleen. Avulsion of mesenteric vessels from the aorta or vena cava, tears along the mesenteric vessels, or avulsion of vessels from the intestines may also occur, as may avulsion of the gallbladder from the liver or avulsion of a cystic duct.

Words of Wisdom

Think of bleeding into the peritoneal cavity as being similar to pouring water into a jar of rocks. Before you see the water at the top of the jar, it must fill in the spaces around the rocks. The same is true of abdominal distention: the blood must fill in the spaces around the organs before you see the swelling or distention. Reassess frequently to ensure that you note changes.

Injuries From Seat Belts and Airbags

Seat belts have prevented many thousands of injuries and saved many lives, including those of people who otherwise would have been ejected during a motor vehicle crash. However, seat belts occasionally cause blunt injuries to the abdominal organs.⁵ When worn properly, a seat belt lies below the anterior superior iliac spines of the pelvis and against the hip joints. If the belt lies too high, it can squeeze abdominal organs or great vessels against the spine when the car suddenly decelerates or stops (**FIGURE 32-6**). Occasionally, fractures of the lumbar spine have been reported. If you are called to the scene of such a crash, keep in mind that the use of seat belts in many cases turns what could have been a fatal injury into a manageable one.

In current-model automobiles, the lap and diagonal (shoulder) safety belts are combined into a single unit so that they may not be used independently. Of course, people can still place the diagonal portion of the belt behind the back; however, this significantly reduces the effectiveness of this design. In some older cars, only lap belts or two separate belts are provided. Used alone, diagonal shoulder safety belts can cause injuries to the upper part of

YOU are the Provider

Part 2

On the basis of the additional information you received from dispatch, you request that the fire department respond for assistance. On arrival at the scene, you find a 32-year-old woman who presents as alert and oriented, with an impaled tree branch in her right upper abdominal quadrant. Surprisingly, the patient is relatively calm and appears in no distress, but she is obviously anxious. She states that she was riding her ATV at approximately 20 miles per hour when it struck a large rock, and she was thrown off the ATV. She landed on some brush and became impaled on a large tree branch. The tree branch is still attached to the tree. Beyond this, she denies any injuries, other than some abdominal pain. She was not wearing a helmet or protective clothing.

Recording Time: 1 Minute

Appearance	Anxious
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent
Breathing	Nonlabored
Circulation	Strong, rapid radial pulses; skin warm and dry

- How do you remove the branch from the wound?
- On the basis of the patient's presentation, does she require spinal immobilization?

FIGURE 32-6 Diagrams (A) and (B) show improper positioning of lap seat belts. The proper position for a seat belt is below the anterior superior iliac spines of the pelvis and against the hip joints, as shown in diagram (C).

© Jones & Bartlett Learning.

the trunk, such as thoracic bruising, fractured ribs, lacerated liver, or even decapitation. Far fewer head and neck injuries are seen when this belt is used in combination with a lap belt and a properly positioned headrest.

The airbag, which is standard equipment in today's vehicles, can be a genuine lifesaver. However, airbags must be used in combination with properly worn safety belts. Small children and short people who are in the front seat of the automobile may be at risk of injury when the airbag is deployed. Special attention should be used in evaluating patients when a deployed airbag is noted. Remember to inspect beneath the airbag for signs of damage to the steering wheel (**FIGURE 32-7**).

Open Abdominal Injuries

An **open abdominal injury** is one in which a foreign object enters the abdomen and opens the peritoneal cavity to the outside (such as a stab wound or gunshot wound). Open abdominal injuries are also

FIGURE 32-7 Raise a deployed air bag to note signs of damage to the steering wheel.

FIGURE 32-8 Because it is difficult to know how deep a penetrating injury is, assume organ damage and transport promptly.

"Penetrating chest trauma secondary to falling on metallic (iron) bar", H. Al-Sayed, H. Sandogji and A. Allam. *Annals of Thoracic Medicine*. © 2009, Wolters Kluwer Medknow.

known as penetrating injuries. Open injuries might not go deeper than the wall of the abdomen, but the depth is often difficult to determine outside of the operating room (**FIGURE 32-8**). Therefore, you must assume the worst—that organs have been damaged—and provide prompt transport.

When a patient has sustained a penetrating injury to the abdomen, it is important to attempt to determine the velocity of the object that penetrated the abdominal wall, because this information can help predict the amount of damage to tissue. Gunshot wounds often cause more injury than stab wounds because bullets travel deep into the body and have more kinetic energy, increasing

the damage lateral to the track of the missile due to temporary cavitation. Gunshot wounds most commonly involve injury to the small bowel, colon, liver, and vascular structures. The extent of injury from gunshot wounds is less predictable than the injury caused by stab wounds, because gunshot wounds depend mostly on the characteristics of the weapon and the characteristics of the bullet.⁶ In penetrating trauma from stab wounds, the liver, small bowel, diaphragm, and colon are the organs most frequently injured.⁷ Do not underestimate the danger of stab wounds, however. They are often rapidly fatal.

Words of Wisdom

The extent of damage from a penetrating injury is often a function of the energy that has been imparted to the body. Remember the following equation:

$$\text{Kinetic energy} = \frac{\text{Mass}}{2} \times \text{Velocity}^2$$

or

$$\text{KE} = \frac{mv^2}{2}$$

An **evisceration** results when a penetrating wound goes all the way through the skin and muscle layer and through the fascia or the interior covering of the abdomen, resulting in bowel protruding through the skin (**FIGURE 32-9**). This visually shocking injury can be extremely painful.

Injuries to Specific Structures

Injury to the Diaphragm

If the diaphragm is penetrated or ruptured, abdominal organs may be pushed upward into the thoracic cavity. Because these will displace lung tissue and vital capacity, patients will exhibit dyspnea or feel short of breath, may have abnormal respiratory sounds, and may have an abdomen with a sunken, concave anterior wall (**scaphoid abdomen**). Patients with this type of injury may require positive-pressure ventilation with a bag-mask device depending on the severity of their respiratory symptoms.

Patients with a ruptured diaphragm after a motor vehicle crash may become very anxious and short of breath if placed in the supine position on a backboard. Change in position from upright to

FIGURE 32-9 An abdominal evisceration is an open abdominal wound from which internal organs or fat protrudes.

© Jonathan Kingston/National Geographic/Getty Images.

supine results in more abdominal contents spilling into the thoracic cavity and compressing the lungs, preventing the lungs from fully expanding. Thus, any injury to the diaphragm will cause signs and symptoms of ventilatory compromise. Note that diaphragmatic injuries or ruptures are not isolated incidents; patients often have associated thoracic, abdominal, head, and extremity injuries.

Injury to the Kidney

Kidneys are the most commonly injured organs of the genitourinary system.⁸ Advanced emergency medical technicians (AEMTs) should consider trauma to these organs whenever a patient has injuries to the lower rib cage, abdomen, pelvis, or upper part of the leg. Injuries to the kidneys generally involve large forces, such as falls from height, high-speed motor vehicle crashes, or sports-related injuries.⁹

Blunt renal trauma results when the kidney becomes compressed against the lower ribs or lumbar spine (as seen in sports injuries, also known as a kidney punch) and when the upper abdomen becomes compressed just below the rib cage (such as

when a child is run over by a car). Contact sports such as football, soccer, hockey, boxing, and rugby are some of the more common culprits in renal injury.¹⁰ Suspect injury to these organs with fractures of the 11th and 12th ribs or flank tenderness. A ruptured kidney will usually present with pain on inspiration in the abdomen and flank areas. The kidneys are highly vascular, and kidney injury may present with blood in the urine (**hematuria**).

Penetrating renal trauma can occur with gunshot or stab wounds in the abdomen or lower chest. A high suspicion for significant injury must be maintained regardless of the site of the entry wound. Penetrating renal trauma is more likely to be associated with injury to the liver, lung, and spleen. For instance, the upward motion of stabbing may cause a renal laceration as well as a pneumothorax. A gunshot wound may result in direct injury to the kidney, but produce greater destruction of the surrounding tissue as a result of the expanding cavity created by the traveling bullet.

Injuries to the kidney rarely occur in isolation because the kidneys lie in the well-protected retroperitoneal space, which is the area behind the true, or anterior, abdomen. Injuries confined to the retroperitoneum can be very difficult to diagnose. In general, this area is remote from physical examination, and an injury there initially does not present with signs and symptoms of peritonitis. Because the blood or other contaminants are held in the retroperitoneal space, they frequently do not cause abdominal pain, peritoneal signs, or abdominal distention.

A penetrating wound that reaches the kidneys almost always involves other organs; the same is true with blunt injuries. A blow that is forceful enough to cause significant kidney damage almost always damages other intra-abdominal organs, often fracturing ribs as well. Less-significant injuries to the kidneys may result from a direct blow or even from a tackle in football (**FIGURE 32-10**). Suspect kidney damage if the patient has a history or physical evidence of any of the following findings:

- An abrasion, laceration, contusion, or hematoma to the flank region
- A penetrating wound in the region below the rib cage and above the hip (the flank) or the upper abdomen
- Fractures on either side of the lower rib cage or of the lower thoracic or upper lumbar vertebrae

FIGURE 32-10 A tackle in football that results in blunt trauma to the lower rib cage or the flank can cause kidney injury.

© jpbcpa/Stock/Getty.

Injury to the Liver

The liver is the largest solid organ in the abdomen and is very vascular; its penetration or rupture may quickly lead to signs of shock. Because of its size and location, the liver is the most vulnerable organ in the abdomen. The superior border of this organ can be as high as the patient's nipples, so a liver injury must be suspected in all patients who have right-side chest trauma as well as abdominal trauma. The liver may be punctured by lower right rib fractures, especially the seventh through ninth ribs. A common finding during assessment of patients with an injured liver is referred pain to the right shoulder.

Injury to the Spleen

The spleen is often injured in motor vehicle crashes, falls, and bicycle or motorcycle collisions, or as the result of penetrating trauma or lower left rib fractures. It is the most commonly injured abdominal organ in blunt trauma in adults and the second most injured abdominal organ in children.¹¹ The potential for rupture is much higher if the spleen is enlarged from mononucleosis or other underlying disease. When the spleen ruptures, large amounts of blood spill into the peritoneum, which can ultimately cause shock and death. Unlike with trauma to the liver, penetrating trauma to the spleen does not present as much of an immediate threat of shock unless a major blood vessel supplying the organ is lacerated. Suspect spleen lacerations when fractures of the 9th through 10th ribs on the left side are present or when the patient reports left upper

quadrant tenderness, hypotension, and tachycardia. It is common for the patient to report left shoulder pain, but this sign does not appear until 1 to 2 hours after the injury.

Special Populations

In pediatric patients, the liver and spleen are large in proportion to the size of the abdominal cavity and are more easily injured. The soft, flexible ribs of infants and young children do not protect these two organs very well.

Injury to the Pancreas

Because of its anatomic position, the pancreas is relatively well protected. It typically takes a high-energy force to damage this organ. Such high-energy forces are most commonly produced by penetrating trauma (eg, from a bullet) but can also be caused by blunt trauma (eg, impact with a steering wheel or handlebars from a motorcycle). Patients with pancreatic injury tend to present with vague upper and midabdominal pain that can radiate into the back. The patient may also develop peritoneal irritation hours after the injury, revealing the presence of traumatic pancreatitis. Some patients have been known to develop a form of diabetes after a severe injury to the pancreas.¹²

Injury to the Intestines and Stomach

The intestines are most commonly injured from penetrating trauma, although they can be injured from severe blunt trauma as well. When ruptured, the intestines spill their contents (which contain fecal matter and a large amount of bacteria) into the peritoneal or retroperitoneal cavities, resulting in peritonitis.

Blunt trauma to the abdominal wall most commonly causes injury to the duodenum because of its location and ligamentous attachment. This type of injury may present as back pain. The duodenum can rupture, spilling its contents into the retroperitoneum. Contamination of the retroperitoneum with duodenal contents may ultimately produce abdominal pain or fever, although symptoms will not likely develop for hours to days. Abdominal pain, nausea, and vomiting may develop, although belatedly. Because of the delayed presentation and

variable symptoms, a high degree of suspicion for duodenal injury must be maintained in any abdominal trauma, but especially in high-speed deceleration crashes. A duodenal injury should be suspected in children who are thrown from a bicycle and strike their abdomen on the handlebars.

Most injuries to the stomach result from penetrating trauma; the stomach is rarely injured from blunt trauma. When rupture of the stomach does occur after blunt trauma, it is usually associated with a recent meal or inappropriate use of a seat belt. Trauma to the stomach frequently results in the spillage of acidic material into the peritoneal space, creating a chemical irritation that produces abdominal pain and peritoneal signs relatively quickly, although patients taking antacid medications may have delayed symptoms.

Trauma to the abdomen may cause injury to the small bowel, the stomach, and the large intestine. The most common cause of such trauma is impact with a seat belt in a motor vehicle collision, because the lap belt lies along the lower quadrant of the abdominal cavity. Symptoms will be caused by the spillage of contents rather than the blood loss. Rupture of the stomach causes rapid, burning epigastric pain; rigidity; and **rebound tenderness**. Small-bowel and colon injury may present with only generalized pain.

Words of Wisdom

Pain may be intense with injuries that result in rupture of the stomach or small bowel, and infection is a delayed complication that may prove fatal.

Injury to the Urinary Bladder

Bladder injuries are usually associated with pelvic fractures from motor vehicle crashes, falls from heights, and physical assaults to the lower abdomen. Injury to the urinary bladder, whether blunt or penetrating, may result in its rupture. Bladder injury should be suspected in any patient with trauma to the lower abdomen or pelvis. Blunt injuries to the lower abdomen or pelvis often cause rupture of the urinary bladder, particularly when the bladder is full and distended. A seat belt that causes contusions to the lower abdomen may also cause blunt trauma to the bladder. Sharp,

FIGURE 32-11 Fracture of the pelvis can result in a laceration of the bladder by the bony fragments. Urine then leaks into the pelvis.

© Jones & Bartlett Learning.

bony fragments from a fracture of the pelvis often perforate the urinary bladder (**FIGURE 32-11**). Penetrating wounds of the lower midabdomen or the perineum (the pelvic floor and associated structures that occupy the pelvic outlet) can directly involve the bladder. In males, sudden deceleration from a motor vehicle or motorcycle crash can literally shear the bladder from the urethra. Trauma to the bladder or urethra is often associated with other significant injuries.

Approximately 20% of bladder injuries occur as a result of a blow to the lower abdomen with a distended bladder.¹³ If a bladder rupture results from sudden deceleration forces, such as those occurring in motor vehicle crashes, urine may be spilled into any part of the abdominal cavity, leading to intraperitoneal, extraperitoneal, or retroperitoneal rupture. When urine spills into surrounding tissues, any urine that passes through the urethra is likely to be bloody.

Injury to the External Male Genitalia

Injuries to the external male genitalia include all types of soft-tissue wounds. Although these injuries are very painful and generally a source of great concern to the patient, they are rarely life threatening. One such injury is testicular torsion, which can occur as a result of trauma. Although it is not life threatening, it is time sensitive and requires rapid transport. These injuries should not be given priority over other, more severe wounds.

Injuries to the Testicle or Scrotal Sac

Severe injuries to the testicles are rare because of their mobility and natural position. Although loss of fertility is the major concern when a patient sustains a testicular injury, the exact outcome depends on whether the testicle can be preserved via definitive treatment in the hospital setting.

Blunt trauma to the testicles or scrotal sac can result from motor vehicle crashes, physical assaults, or sports injuries. Blunt testicular trauma can result in simple contusions, rupture of the testicle, and, in rare cases, torsion (twisting) of the testicle. Most testicular ruptures occur in sports participants. Testicular injuries frequently present following trauma to the thighs, buttocks, penis, lower abdomen, and pelvis.

Penetrating trauma to the testicles or scrotal sac may result from stab wounds, gunshot wounds, blast wounds, or animal bites. You should have a high suspicion for other associated injuries in cases of obvious penetrating trauma.

Penis Injuries

The penis is a vital organ for both proper urination and sexual function. Injuries to the penis may result from blunt or penetrating trauma but also may arise from sexual behavior or self-mutilation. Physiologically, the penis becomes erect when blood fills the corpus cavernosa. Priapism—a painful, tender, persistent erection—can have nontraumatic causes, such as sickle cell disease.

A fractured penis may occur when an erect penis is accidentally impacted against the partner's pubic symphysis or bent too far via self-manipulation.

Penetrating trauma to the penis most often results from gunshot wounds. Self-mutilation or amputation may also be a cause. Typically, this type of injury occurs in patients with significant psychiatric disorders.

Injury to the Female Genitalia

Internal Female Genitalia

The uterus, ovaries, and fallopian tubes are subject to the same kinds of injuries as any other internal organ. However, they are rarely damaged because they are small, deep in the pelvis, and well protected by the pelvic bones. Unlike the bladder, which lies adjacent to the bony pelvis, they are usually not

injured in a pelvic fracture. Penetrating trauma to the reproductive organs may result from stabbings to the lower pelvis or gunshot wounds. Because the path of a bullet cannot be predicted from the entry wound alone, any injuries to the abdomen or upper legs also may have damaged the reproductive organs.

An exception is the pregnant uterus. As pregnancy progresses, the uterus enlarges substantially and rises out of the pelvis, becoming vulnerable to penetrating and blunt injuries. These injuries can be particularly severe because the uterus has a rich blood supply during pregnancy, even though the injuries may be masked initially owing to the increased blood volume during pregnancy. You must also keep in mind that another life, that of the unborn child, is at risk. You can expect to see the signs and symptoms of shock with pregnant patients; be prepared to provide all necessary support and prompt transport. Note that contractions may begin as well. If possible, ask the patient when she is due, and report this information to hospital staff.

In the last trimester of pregnancy, the uterus is large and may obstruct the inferior vena cava, decreasing the amount of blood returning to the heart if the patient is placed in a supine position (**supine hypotensive syndrome**). As a result, blood pressure may decrease. The patient should be carefully placed on her left side so that the uterus will not lie on the vena cava. If the patient is secured to a backboard, tilt the board to the left. Care for pregnant patients is described in greater detail in Chapter 35, *Obstetrics and Neonatal Care*.

External Female Genitalia

The external female genitalia include the vulva, the clitoris, and the major and minor labia (lips) at the entrance of the vagina. Injuries to the external female genitalia can include all types of soft-tissue injuries.

In any case of trauma, it is important to attempt to determine the possibility of pregnancy. It will be important to ask the patient for the date of her last known menstrual period or if she has been sexually active. The assumption is that all women of childbearing age are possibly pregnant. This information is medically relevant because some medications and tests are harmful for a fetus, and there is the potential for another source of blood loss in the gravid uterus.

Vascular Injuries

In addition to the kidneys, the vascular structures found in the retroperitoneal space include the descending aorta (and its branches), the superior and inferior phrenic arteries, the inferior vena cava, and the mesenteric vessels. Injuries to these structures occur with both blunt and penetrating trauma, but penetrating trauma that causes injury to the great vessels of the abdomen will also be associated with injuries to multiple intra-abdominal organs. Blunt trauma can cause injuries to vascular structures in the intraperitoneal space as they are sheared from their points of attachment.

Vascular injuries are often masked by other injuries. The significance of the injury depends on how many vessels were injured and the length of time that has passed since the injury occurred. Assessment findings in a patient with vascular injuries differ depending on whether the bleeding is contained (a hematoma) or there is active hemorrhage. In active hemorrhage, the patient will present with significant hypotension, tachycardia, and shock.

The intestinal blood supply comes from the mesentery. The term *mesentery* refers to any fold of tissue that attaches an organ to the body wall. The intestinal mesentery, therefore, is a fold of tissue that contains a web of blood vessels, as well as nerves and lymphatic tissues; it connects the small intestine to the posterior of the abdominal wall. Blunt and penetrating abdominal injuries affect this vasculature, and patients with injuries to the mesentery can bleed significantly into the peritoneal cavity. A common sign of bleeding in the abdomen is rigidity, with an almost boardlike feeling to the abdomen. Occasionally you will find periumbilical bruising or ecchymosis (Cullen sign).

Sometimes a patient may have an **abdominal aortic aneurysm (AAA)** that has developed and become worse as a result of abdominal trauma. The presence of a pulsating mass near the umbilicus is indicative of an AAA. Remember to palpate *gently* when assessing the abdomen of a patient with a history of or presence of an AAA.

Rectal bleeding is a common complaint and something that you may encounter as a chief complaint or secondary to abdominal or pelvic complaints. Bleeding from the rectum may present as blood stains or blood soaking through underwear or patients may report blood in the toilet after a

bowel movement or attempted bowel movement. Rectal bleeding can be caused by a sexual assault, rectal foreign bodies, hemorrhoids, colitis, or ulcers of the digestive tract. Significant rectal bleeding can occur after hemorrhoid surgery and can lead to significant blood loss and shock.

Patient Assessment

Although the cause of an abdominal or genitourinary injury may be readily apparent as a result of the MOI or the visibility of a penetrating wound, the resulting damage may not be so apparent. Often, other injuries, such as a fractured bone, may be painful and distracting for the patient. The patient may not tell you about more subtle pain that could indicate an abdominal or genitourinary injury. In addition, some abdominal or genitourinary injuries develop and worsen over time, making reassessment critical.

When you are assessing a genitourinary injury, there is a potential for embarrassing the patient. Therefore, you need to maintain a professional presence at all times when treating these injuries. Remember to provide privacy for the patient during the assessment process. When examining the patient, expose only what is needed and then cover what has been exposed. Whenever possible, have an AEMT of the same sex as the patient perform the assessment. You will need to look for blood on the patient's underwear and inspect the external genitalia when there are complaints of pain or external signs of injury.

Scene Size-up

As with any situation, scene safety is your first consideration. Remember to follow standard precautions because these injuries often bleed profusely, and even if they do not, some blood or other body fluid is likely to be present. Eye protection is required when managing open injuries. Observe the scene for hazards and threats to your safety. If dispatch information indicates a possible assault, domestic dispute, or shooting (all of which commonly lead to abdominal injuries) be sure that law enforcement personnel have controlled the scene.

Look for indicators of the MOI, and consider early spinal precautions. This approach helps you develop an early index of suspicion for underlying

injuries in a patient who has sustained a significant MOI. As you put together information from dispatch and your observations of the scene, consider the possible injuries the MOI could have produced. As you inspect a vehicle, look at the damage. Could this damage result in an abdominal injury? In the case of an assault, think about how many times the patient was struck, with what object, and where the patient was struck. Information from the scene will help to determine your index of suspicion.

If the wound is penetrating, inspect the object of penetration. Is the object's edge serrated, smooth, or jagged? Is it clean or dirty? The MOI may also provide indications of potential safety threats. For example, a knife wound may indicate the presence of a violent person.

With genitourinary injuries, be aware that the patient may avoid discussing the injury to avoid undergoing a physical examination. Also, the patient may provide an MOI that seems "less embarrassing" than the actual MOI. By maintaining a professional demeanor, respecting the patient's privacy, and maintaining the patient's dignity, you will earn the patient's trust. If the patient trusts you, you are more likely to learn the true facts behind the injury.

Primary Survey

Your goal during the primary survey is to evaluate the patient's airway, breathing, circulation, disability, and exposure (ABCDEs) and then immediately care for any life threats. Control any external hemorrhage, and look for indication of internal bleeding. Abdominal injuries may be overlooked in multisystem injuries, so it is important to maintain a high index of suspicion for abdominal injuries based on the MOI. The evaluation of a patient who has abdominal or genitourinary trauma must be systematic, keeping the entire patient in mind and prioritizing accordingly.

In trauma patients, life-threatening external hemorrhage must be addressed before airway or breathing concerns; follow the XABCDE mnemonic, assessing and managing exsanguinating hemorrhage immediately after establishing scene safety. Next, ensure the patient has a clear and patent airway. If a spinal injury is suspected, prevent the patient from moving by having a team member manually stabilize the patient's head and verbally remind the patient not

to move. Patients may report feeling nauseated, and they may vomit. Remember to keep the airway clear of vomitus so that it is not aspirated into the lungs, especially in a patient who is unresponsive or has an altered level of consciousness. Turn the patient on one side, stabilizing the spine if necessary, and try to clear any material from the throat and mouth. Note the nature of the vomitus: undigested food, blood, mucus, or bile.

You must also quickly assess the patient for adequate breathing. A distended abdomen or pain may prevent adequate inhalation. When these guarded respirations decrease the effectiveness of the patient's breathing, providing supplemental oxygen with a nonrebreathing mask will help improve oxygenation. If the patient's level of consciousness is decreased and respirations are shallow, consider supplementing respirations with a bag-mask device.

All abdominal organs have a generous blood supply, so an injury to the abdomen can be fatal because of hemorrhage. Retroperitoneal hemorrhage may be present because of damaged muscle, lacerated or avulsed kidneys, and injuries to the vessels of the supporting mesentery. If visible significant bleeding is seen, you must begin the steps necessary to control bleeding. Recall that significant bleeding is an immediate life threat and must be controlled quickly using appropriate methods, even before addressing airway and breathing concerns. In dark environments, bleeding can be difficult to see. Thick clothing may also hide bleeding. After you consider the MOI and form suspicions as to where bleeding may occur, expose that part of the body.

Evaluate the patient's pulse and skin color, temperature, and condition. If you suspect shock, treat the patient for shock according to your protocols.

Early Assessment of the Abdomen

With significant trauma, you should perform a rapid full-body scan of the patient. If the patient has been subjected to a significant MOI, a rapid full-body scan will help you to quickly identify any injuries the patient may have, not just abdominal injuries. Begin with the head, and finish with the lower extremities, moving in a systematic manner. Your goal is not to identify the extent of all the injuries, but to determine whether other injuries are present. This requires you to work quickly but thoroughly. If you

find a life-threatening problem during this scan, stop and treat it immediately; otherwise, move on. The injuries you find will help you in packaging the patient for transport.

Examine the abdomen closely looking for DCAP-BTLS (Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, Swelling). All of these may be signs of **hemoperitoneum**—that is, collection of blood in the abdominal cavity. Clues to intra-abdominal trauma will include symptoms of shock not proportional to obvious external evidence or estimated blood loss. During palpation, involuntary muscle guarding and reaction to sudden, jarring movements are reliable signs of peritoneal irritation. Or, you may note rebound tenderness (pain that the patient feels when pressure is released as opposed to when pressure is applied); it is characteristic of the pain associated with peritonitis.

History Taking

Once you have identified and treated life threats, you can then move on to gathering a history from the patient. If you have not yet done so, you should determine and investigate the patient's chief complaint and further investigate the MOI. You will also identify any associated signs and symptoms and pertinent negatives.

Obtain a history of the present illness using the OPQRST-I mnemonic (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, Interventions), and a past medical history using the SAMPLE mnemonic (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) from the patient. Using OPQRST-I to help explain an abdominal injury may provide some helpful information, such as the description of the pain and whether the pain is radiating. If the patient is not responsive, attempt to obtain the SAMPLE history from friends or family members.

Be sure to ask whether the patient has experienced any nausea, vomiting, or diarrhea. If the patient has experienced any of these symptoms, ask how many times and during which time period. Ask about the appearance of any bowel movements and urinary output to check for any blood in the urine, black tarry stools (**melena**), or the presence of blood in the stools (**hematochezia**). This information can

help to determine whether the patient has gastrointestinal bleeding. In addition, note the presence of any rectal bleeding.

The incidence of repeated or previous injury or illness involving the genitourinary system can help determine the extent of the current injury and possibly the MOI. The last intake of food and fluids is important because it can help to predict what is contained in the genitourinary system and whether the symptoms are related to the ingestion of those foods and fluids.

Words of Wisdom

Obtaining a good patient history that includes medications being taken may help to increase your index of suspicion for significant injury. For example, a patient taking a beta-blocker or using a constant pacemaker will not necessarily have the increase in pulse associated with shock.

Secondary Assessment

The secondary assessment may need to be performed en route to the emergency department (ED). If you have not already done so, obtain a full set of vital signs—including pulse rate, blood pressure, respirations, oxygen saturation, mental status, skin condition, and pupils. Each of these is considered an indication of how the patient is tolerating the injuries.

Many abdominal emergencies, in addition to those that cause severe bleeding, can cause a rapid pulse and low blood pressure. Your record of vital signs, made as early as possible and periodically thereafter (every 5 minutes in a patient whom you suspect has a serious injury), will help you to identify changes in the patient's condition and be alert to signs of decompensation from blood loss. If the patient is experiencing external or internal hemorrhaging, as in the case of a stab wound or a direct blow to the abdomen, monitor the vital signs closely with a degree of suspicion and pay close attention to shifts in the vital signs. Signs such as tachycardia; tachypnea; low blood pressure; weak pulse; and cool, moist, and pale skin indicate hypoperfusion and imply the need for rapid treatment at the hospital.

In a patient who has an isolated injury to the abdomen with a limited MOI, such as in a stabbing, you should focus your assessment on the isolated injury, the patient's complaint, and the body region affected. However, usually, you will perform the physical examination on all patients with abdominal injuries in the same manner:

- Remove or loosen clothes to expose the injured regions of the body. Inspect the patient for bleeding again before removing the patient's clothing to prevent damaging any exposed tissues such as in the case of an evisceration.
- Provide privacy as needed, or wait until you are in the back of the ambulance.
- A patient without suspected spinal injury should be allowed to stay in the position of comfort—with the legs pulled up toward the abdomen. This position will relieve some of the tension on the abdomen and, therefore, provide pain relief.
- For patients with spinal injury, place padding such as blankets or pillows under the patient's knees to help alleviate tension on the abdominal wall. Keep in mind that you can worsen the spinal injury if you are too aggressive when placing these items.

Examine the entire abdomen, including all posterior, anterior, and lateral surfaces. This is a critical step when patients have an injury with an entrance wound. Examine the axillae (armpits) for entrance wounds.

When you auscultate the bowel, keep in mind that in the prehospital setting, bowel sounds can be difficult to hear, difficult to interpret, and diverse in cause. Blood, gastrointestinal contents, and urine that have spilled into the peritoneum may produce peritonitis that could result in decreased or absent abdominal sounds. Maintain a high index of suspicion, and provide early treatment for shock.

Look for the presence of contusions and abrasions, which can help localize focal points of impact and may indicate significant internal injury. Bruises or other visible marks are important clues to the cause and severity of any blunt injury. Steering wheels and seat belts produce characteristic patterns of bruising on the abdomen or chest. Note the presence of any burns, and manage them appropriately. Identify and treat any lacerations with appropriate dressings. Swelling may involve the

Words of Wisdom

Assess the abdomen for the following:

- DCAP-BTLS
- Distention
- Rigidity
- Guarding
- Rebound tenderness

abdomen globally and indicate significant intra-abdominal injury.

Next, inspect the skin of the abdomen for holes (puncture wounds) through which bullets, knives, or other missile-type foreign bodies may have passed. Keep in mind that the size of the wound does not necessarily indicate the extent of underlying injuries. If you find an entry wound, you must always check for a corresponding exit wound in the patient's back or sides. If the injury was caused by a high-velocity missile from a rifle, you may see a small, harmless-looking entrance wound with a large, gaping exit wound. Do not attempt to remove a knife or other object that is impaled in the patient. Instead, stabilize the object with bulky dressings and supportive bandaging.

The kidneys are located in the flank region of the back. Inspect and palpate this area for tenderness, bruising, swelling, and other signs of trauma. Although you may not be able to elicit pain from the specific organ, the tissues around it may exhibit symptoms of pain.

Up to this point in the patient assessment process, you may have been stabilizing the patient's spine by simply holding the head still and telling the patient not to move. If a cervical collar has not been applied, place one on the patient now before you log roll the patient to inspect the posterior part of the body and place the patient on a backboard. Penetrating trauma alone is not an indication for spinal immobilization. For example, time should not be wasted immobilizing a patient who has penetrating trauma to the head, neck, or torso.¹⁴

Finally, note whether the patient has hematuria (blood in the urine). This is a cardinal sign of renal and urinary tract injury, which can occur when renal or urinary vessels rupture, or when blood is able to enter the urine during glomerular filtration. Note the color of the urine: a darker brown suggests bleeding in the upper urinary tract, whereas a brighter red is most likely due to bleeding in the lower portion of the tract.

YOU are the Provider

Part 3

Once fire department personnel arrive on scene, you consult with the officer in charge on the engine and request that the branch be cut approximately 12 inches (30 cm) from the patient, making sure that extreme care is taken to minimize movement of the branch. Your partner maintains manual stabilization of the patient's head while you apply a cervical collar. While the fire department personnel are preparing their equipment, you insert a single 18-gauge IV line.

Recording Time: 8 Minutes

Respirations	22 breaths/min; normal
Pulse	Strong and rapid; 122 beats/min
Skin	Cool, pale, and clammy
Blood pressure	78/46 mm Hg
Oxygen saturation (SpO₂)	100% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. Does this patient require a second IV line?
6. Once the tree branch is cut free from the tree, how do you secure it?

Pain Assessment

A common misconception is that patients without abdominal pain or abnormal vital signs are unlikely to have serious intra-abdominal injuries. In reality, peritonitis can take hours to days to develop. Similarly, nonspecific symptoms such as hypotension, tachycardia, and confusion may not develop until the patient has lost more than 40% of the circulating blood volume.¹⁵ Always maintain a high index of suspicion in any patient who has an MOI consistent with abdominal trauma, regardless of the examination findings. Abdominal distention is a late indication of abdominal trauma. Patients must have a significant volume of blood enter the abdominal cavity to fill it and produce distention.

Words of Wisdom

Log rolling the patient onto a backboard is a valuable opportunity to examine the back for signs of injury. Instruct and position assistants to ensure your ability to inspect and palpate the back briefly while the patient is rolled onto the side.

If possible, pad the backboard before returning the patient to a supine position. This helps reduce discomfort and prevents aggravating soft-tissue injuries.

Avoid log rolling patients with an evisceration because this movement can cause more of the intestines to protrude from the wound. Instead, keep the patient in the supine position and allow the patient to flex the knees when possible to help relieve tension on the abdomen. A scoop stretcher is an option for lifting the patient in this case.

Quickly assess the patient's condition with a simple inspection, noting the manner in which the person is lying. Movement of the body or the abdominal organs irritates the inflamed peritoneum, causing additional pain. To minimize this pain, patients may lie still, usually with the knees drawn up, and breathe using rapid and shallow breaths. For the same reason, they may contract abdominal muscles (guarding).

Assess the patient's pain. **Somatic pain** comes from skin and muscle, as well as joints, ligaments, and tendons. It is often described as sharp and localized to the area of injury. Bleeding, swelling, and cramping may exist with somatic pain. This pain

usually responds well to medications such as opioids and nonsteroidal anti-inflammatory drugs. **Visceral pain** comes from organs inside the body with injury or illness. This type of pain travels from pain receptors in the nerves running throughout the body. The pain receptors transfer the information to the brain, where the pain is then perceived. Visceral pain can radiate to other locations such as the back and chest. There are three main areas where visceral pain is felt: the thorax, abdomen, and pelvis. Such pain is often described as a deep ache with cramping.

Because pain is a common symptom in abdominal and urologic ailments, it is often difficult to determine the source of the pain. Do not waste valuable time trying to determine the exact cause of the pain in the prehospital setting.

Abdominal pain together with an MOI that suggests injury to the abdomen or flank is a good

Special Populations

Pregnant patients pose special challenges. Traumatic injuries to pregnant patients can be further complicated by the physiologic changes experienced by the patient. Some changes can mimic shock. For example, the pregnant patient's heart rate can increase by as much as 20 beats/min, blood volume can increase by as much as 50% during midpregnancy, and a pregnant woman can experience relative anemia from hemodilution (hemoglobin remains steady while fluid volume increases).¹⁶ Due to the increase in blood flow to the uterus, the risk for massive blood loss is greatly increased with trauma to the bony pelvis. At term, the placenta/uterus can perfuse approximately 600 to 800 mL of blood per minute.

Treatment of pregnant patients should always start with the ABCs. There is a higher risk of aspiration and increase in gastric acidity. All pregnant patients should receive maximum oxygenation because of increased oxygen consumption and reduced reserve. Hypoxia can cause a 30% reduction in uterine blood flow.¹⁷ Also, remember that if the pregnant patient is at more than 20 weeks' gestation, she should be tilted at least 15° to her left to prevent supine hypotensive syndrome, which can result from pressure on the inferior vena cava. This may be accomplished by placing blankets or other padding material underneath the backboard. If the patient is secured to a long backboard, towel rolls can be placed under the backboard to accomplish the tilting.

indication for rapid transport. Transport to a trauma center is indicated for any patient who has an MOI that produces a high index of suspicion and who has any visible significant trauma, whether blunt or penetrating. Do not delay transport of a seriously injured trauma patient to complete non-life-saving treatments such as splinting extremity fractures. Instead, complete these types of treatments en route to the hospital to the extent feasible.

Assessment Pearls

- Consider intra-abdominal bleeding in any patient showing signs and symptoms of shock with no signs of obvious injury.
- For a patient with a scaphoid abdomen, elevate the head of the backboard 30° to assist with ventilation.
- Consider any stab wound at the nipple line or below to have potential for injury to upper abdominal organs depending on direction of travel and length of the weapon.
- Any stab wound at the level of the umbilicus or higher may also penetrate the thoracic cavity.
- Always consider the MOI, regardless of patient presentation! Not all injuries are obvious.
- Monitor the airway closely and be alert for vomiting in any patient with abdominal injury.
- Never rule out underlying injury when obvious signs and symptoms are not present. A patient may decompensate before signs appear.
- Treat early and aggressively for shock.
- Consider all blunt trauma to the flank area to involve the kidneys.

Reassessment

Repeat the patient's primary survey and reassess vital signs. Reassess the interventions and treatment you have provided to the patient. Identifying trends in pain, vital signs, and the progress of treatments will help determine whether the patient's condition is improving or getting worse. Adjustments in care can be based on these objective findings.

Communicate the MOI and injuries found during your assessment, so the hospital staff will be prepared for the patient. Documentation of your assessment and the trends in vital signs is also a tremendous help to physicians in evaluating

the problem when the patient arrives in the ED. Document the results of the physical examination and any pertinent negatives such as no blood loss noted in bowel movements. Also document any step of the physical examination that you skipped, such as opting not to perform palpation on a patient with acute abdominal pain. It is imperative that you be able to describe the scene in enough detail so the trauma team has a clear idea of the circumstances surrounding the event. Some services and departments now carry digital or other instant cameras that enable AEMTs to show the MOI to the trauma team.

If assault is suspected, you may have a legal requirement to inform the hospital staff of your suspicions; however, this information can wait until you have delivered the patient to the hospital and have a chance to discuss it privately with appropriate hospital personnel.

Be cautious and diligent when dealing with patients who refuse transport to the hospital after sustaining an injury to the abdomen or genitourinary system. Patients with these injuries are at high risk for complications; therefore, that information should be explained to them in great detail. Contacting medical control for assistance to convince the patient of the need for transport can be very useful. If the patient continues to refuse transport, have the patient sign a document of refusal or an "against medical advice" form.

Assessment and Management of Specific Injuries

Patients presenting with blunt injury and evidence of substantial abdominal trauma are potentially not reliable based on the distracting nature of the abdominal injury. Based on mechanism, therefore, they should undergo spinal immobilization or spinal motion restriction. If there is no suspected spinal trauma involved and the patient is reliable, the patient may be placed in a position of comfort. High-flow oxygen should also be administered. Cover the patient to maintain warmth. Consider the use of a pneumatic antishock garment (PASG) for an unstable pelvis if dictated by local protocol.¹⁸ Use of PASGs is controversial; see Chapter 27, *Bleeding*, for further discussion.

Most abdominal trauma requires rapid transport to the closest, most appropriate facility. Surgery

is often the required definitive care for these injuries. Provide emotional and psychological support en route. For AEMT units, consider calling for paramedic mutual aid. Call your report in to the ED as soon as possible to allow for preparation for your arrival. Complete your documentation thoroughly and as soon as possible after transferring the patient to the ED.

Closed/Blunt Abdominal Injuries

Patients with abdominal injuries generally have one principal complaint: pain. However, other significant injuries may mask the pain at first, and some patients may not be able to tell you about pain because they are unresponsive, such as after a head injury or drug or alcohol overdose. Common symptoms include abdominal tenderness, particularly localized tenderness, and difficulty with movement because of pain.

The most common sign of significant abdominal injury is tachycardia. The patient may also present with tachypnea and signs of agitation. It is important to note these signs early, before later signs of shock appear, such as decreased blood pressure and pale, cool, moist skin. In some cases, the abdomen may become distended from the accumulation of blood and fluid.

In addition to the general signs already mentioned, signs and symptoms of blunt injuries include bruises or other visible marks, whose location should guide your attention to underlying structures. Crepitus in the lower rib areas may indicate broken ribs that have the potential to puncture underlying organs. In patients with liver and spleen injuries, where there is bleeding into the peritoneal space, pain is referred to the shoulder. This finding is called the **Kehr sign** when it involves injury to the spleen and pain in the tip of the left shoulder. However, shoulder pain can be misleading, and injury to the liver or spleen could possibly be overlooked if the shoulder is also injured or if the MOI suggests that an impact or injury may have occurred in the shoulder girdle.

Pay attention to the patient's description of pain.

- Pain that is tearing and described as going from the abdomen posteriorly is often describing symptoms of an abdominal aneurysm that is undergoing dissection.

- Pain that follows the angle from the lateral part of the hip to the midline of the groin can be the result of damage to the kidneys or the ureters.
- Pain primarily located in the right lower quadrant can indicate an inflamed or ruptured appendix.
- Pain from the gallbladder due to direct injury or inflammation can be found just under the margin of the ribs on the right side or between the shoulder blades.

Determining the location of the pain or referred pain can be more difficult when the patient has voluntary or involuntary **guarding**. In guarding, the patient intentionally or unintentionally stiffens the muscles of the surface of the abdomen. Most often it is the rectus abdominis muscles (that run from the pubis to the xiphoid process) that are held tight, and the tightness can be mistaken for abdominal rigidity. This stiffening is a natural response to abdominal pain; the body is attempting to splint the area to prevent unnecessary movement and to avoid further pain.

Depending on the MOI, such as an assault or a vehicle-versus-pedestrian crash, closed abdominal injuries may initially appear as abrasions to the surface of the skin. In some circumstances, depending on how deep in the abdomen the injury occurs, it may take several minutes to hours for the contusion or hematoma to become present on the surface. In other circumstances, these signs may never develop despite the presence of severe underlying injuries.

The signs of abdominal injury are usually more indicative of the specific injury than the symptoms, including firmness on palpation of the abdomen; obvious penetrating wounds; bruises; and altered

Words of Wisdom

Both the Cullen sign and the Grey Turner sign are caused by intra-abdominal bleeding found 12 to 24 hours after the initial injury. The presence of these signs is helpful, but their absence does not rule out life-threatening abdominal hemorrhage.

- Cullen sign is a black and blue discoloration (ecchymosis) in the umbilical region caused by peritoneal bleeding.
- Grey Turner sign includes ecchymosis present in the lower abdominal and flank regions.

vital signs, such as tachycardia, tachypnea, hypotension, and shallow respirations (although these signs might not appear until later). For example, bruises in the right upper quadrant, left upper quadrant, or **flank** (region below the rib cage and above the hip), called the Grey Turner sign, might suggest an injury to the liver, spleen, or kidney, respectively (**FIGURE 32-12**). Bruises around the umbilicus (**Cullen sign**) are predictive of significant internal abdominal bleeding (**FIGURE 32-13**).

A patient with a blunt abdominal injury may have one or some combination of the following:

- Severe bruises of the abdominal wall
- Laceration of the liver and spleen

FIGURE 32-12 Bruises in the right upper quadrant, left upper quadrant, or flank, called the Grey Turner sign, suggest an injury to the liver, spleen, or kidney, respectively.

- Rupture of the intestine, gallbladder, or stomach
- Tears in the mesentery
- Rupture of the kidneys or avulsion of the kidneys from their supporting structures
- Rupture of the urinary bladder, especially in a patient who had a full and distended bladder at the time of injury (for example, a patient who had been drinking)
- Severe intra-abdominal hemorrhage
- Peritoneal irritation and inflammation in response to the rupture of hollow organs

If you suspect injury to the diaphragm, focus on the airway, breathing, and circulatory status of the patient. Signs and symptoms of a diaphragmatic rupture can include abdominal pain, acute respiratory distress, decreased breath sounds, abdominal sounds in the chest, subcutaneous emphysema, and a scaphoid abdomen (a sunken abdomen or an abdomen that appears empty). Examine the patient's neck and chest, paying particular attention to the trachea (tracheal deviation due to mediastinal shift), symmetry of the chest during expansion, and absence of breath sounds.

Immobilize any patient who has sustained a blunt abdominal injury when indicated by MOI and/or patient presentation. If the patient vomits, turn the patient to one side and clear the mouth and throat of vomitus. Monitor the patient's vital signs for any indication of shock, such as pallor, diaphoresis, low blood pressure, and rapid, thready pulse. If you see any of these signs, administer supplemental oxygen via a nonbreathing mask or provide positive-pressure ventilation via a bag-mask device if needed and take all the appropriate measures to treat for shock. Keep the patient warm with blankets, and provide prompt transport to the ED.

Open/Penetrating Abdominal Injuries

Patients with penetrating injuries generally have obvious wounds and external bleeding (**FIGURE 32-14A**). A large wound may have bowel, fat, or a fold of peritoneum protruding from it. In addition to pain, patients often report nausea and vomiting.

Many signs and symptoms of closed abdominal wounds may also be present along with puncture wounds. A very common sign of significant

abdominal injury is tachycardia because the heart is increasing its pumping action to compensate for blood loss, an early indication of compensated blood loss. Later signs include evidence of shock, such as decreased blood pressure; pale, cool, and moist skin; or changes in the patient's mental status, combined with trauma to the abdomen. In some cases, the abdomen may become distended from the accumulation of blood and fluid. Keep in

mind that puncture wounds made by a hand-driven weapon (such as a knife) may create significant damage based on the direction of travel and whether the weapon was moved around inside the wound. Wounds created by medium- and high-velocity weapons can produce increased areas of damage due to areas of cavitation (cavity formation). Cavitation can produce significant bleeding, depending on the speed or velocity of the penetrating object.

**A****B**

FIGURE 32-14 A. Penetrating injuries have obvious wounds and may also have external bleeding. **B.** If the penetrating object is still in place, use bulky dressings and a roller bandage to stabilize the object and to control bleeding.

YOU are the Provider

Part 4

On the basis of the patient's vital signs and physical examination findings, you elect to insert a second IV line and administer four sequential 250-mL boluses of normal saline, checking the blood pressure after each bolus and stopping the boluses once systolic blood pressure exceeds 80 mm Hg. Once the fire department personnel have cut the branch free from the tree, you pad around the branch with multiple bulky dressings and roller gauze in an attempt to secure it. With the assistance of everyone on scene, you secure the patient to a long backboard and initiate rapid transport to the local Level I trauma center, approximately 9 minutes away. The remainder of the transport is uneventful, with the patient's vital signs stabilizing with a blood pressure above 80 mm Hg systolic.

Recording Time: 14 Minutes

Respirations	20 breaths/min; normal
Pulse	Strong and regular; 100 beats/min
Skin	Warm and dry
Blood pressure	92/60 mm Hg (after initial 250-mL fluid bolus)
Oxygen saturation (SpO₂)	100% with oxygen at 15 L/min via nonrebreathing mask
Pupils	PERRLA

- Does this patient require evaluation at a trauma center, or should she be transported to the closest facility for evaluation first?

TABLE 32-1 Penetrating Trauma: Velocity and Resulting Cavitation

Velocity	Type of Weapon	Cavitation
Low energy	Hand-driven weapons such as knives, scissors, and ice picks	There is minimal cavitation, and the damage is only by the cutting edge.
Medium energy	Low-velocity weapons such as handguns and low-powered firearms (such as .38 special, .45 ATC [authorization to carry]) in which the muzzle velocity is less than 1,500 feet per second	The projectile is small, and cavitation is 6 to 10 times the bullet's frontal area.
High energy	High-velocity weapons such as high-powered rifles and military high-velocity, small-caliber weapons such as M16, AK-47, which have a muzzle velocity of greater than 1,500 feet per second	Cavitation is 20 to 30 times the frontal area of the missile.

© Jones & Bartlett Learning.

If major blood vessels are cut or solid organs are lacerated, bleeding may be rapid and severe. Other signs of intra-abdominal injuries may develop slowly, particularly in penetrating wounds to hollow organs. Once such an organ is punctured and its contents are discharged into the abdominal cavity, peritonitis may develop, but this may take several hours.

Some penetrating injuries go no deeper than the abdominal wall, but the severity of the injury can be difficult to determine. Only a surgeon can accurately assess the damage. Therefore, as you care for a patient with this type of wound, you should assume that the object has penetrated the peritoneum, entered the abdominal cavity, and possibly injured one or more organs, even if there are no immediate obvious signs. Low-, medium-, and high-velocity penetrating trauma are outlined in **TABLE 32-1**. See Chapter 26, *Trauma Overview*, for more information.

In caring for a patient with a penetrating wound of the abdomen, follow the general procedures previously described for care of a blunt abdominal wound, as well as the following specific steps for the penetrating wound: inspect the patient's back and sides for exit wounds, and apply a dry, sterile dressing to all open wounds.

If the penetrating object is still in place, do not remove it. Expose the wound. Then, while manually stabilizing the object in its position, apply bulky dressings around it to control external bleeding, and then secure the dressings in place with a stabilizing

bandage, which will minimize movement of the object (**FIGURE 32-14B**).

Initiate two 18-gauge IV lines or larger or follow local protocol, and administer isotonic crystalloid solutions to deliver sequential 250-mL boluses (up to a maximum of four) or the amount needed to obtain a systolic blood pressure of 80 mm Hg. Increasing blood pressure can increase internal bleeding, so fluid should be given in a volume to maintain perfusion to vital organs.

Words of Wisdom

The only reason to remove an impaled object is when it is through the cheek and interferes with breathing or maintaining an airway, or when it is in the chest and interferes with cardiopulmonary resuscitation.

Abdominal Evisceration

During assessment of an evisceration, do not push down on the patient's abdomen. Perform only a visual assessment when there is any suspicion of this type of injury. If there is clothing close to the wound, carefully cut the clothing around the wound, leaving a border of intact cloth outside the injured area. Never pull, even gently, on any clothing stuck to or in the wound channel because this may remove even more of the organ.

When you are caring for an evisceration, never try to replace an organ that is protruding from the

abdomen, whether it is a small fold of peritoneum or nearly all of the intestines. Instead, cover it with sterile gauze compresses moistened with sterile saline solution, and secure them with a dry, sterile dressing. (Protocols in some EMS systems call for an occlusive dressing over the organs, secured by trauma dressings.)

Because the open abdomen radiates body heat very effectively and because exposed organs lose fluid rapidly, you must keep the organs moist and warm. If you do not have gauze compresses, you may use moist, sterile dressings, covered and secured in place with a bandage and tape (**FIGURE 32-15**). Do not use any material that is adherent or loses its substance when wet, such as toilet paper, facial tissue, paper towels, or absorbent cotton.

Once you have covered the extruding organ, you should provide other emergency care as necessary and provide prompt transport to the ED. Treat the patient for shock by keeping the patient warm and, if possible, placing the patient in the position dictated by local protocol for shock patients. Provide high-flow oxygen and transport according to local protocols and destination policy. Transport the patient to the highest-level trauma center available.

Words of Wisdom

Anything that is normally located within the body must be kept moist when it is outside the body. Cover eviscerated organs with sterile, moist dressings.

Kidneys

Damage to the kidneys may not be obvious on inspection of the patient. You may or may not see bruises or lacerations on the overlying skin. However, you will see signs of shock if the injury is associated with significant blood loss. Because one of the functions of the kidney is the formation of urine, another sign of kidney damage is blood in the urine (hematuria). Treat shock and associated injuries in the appropriate manner. Provide prompt transport to the hospital, monitoring the patient's vital signs carefully en route.

Urinary Bladder

Suspect a possible injury to the urinary bladder if you see blood at the urethral opening or physical

FIGURE 32-15 **A.** The open abdomen radiates body heat rapidly and must be covered. **B.** Cover the wound with moistened, sterile dressings and with an occlusive dressing, depending on local protocol. **C.** Secure the dressing with a bandage. **D.** Secure the bandage with tape.

© Jones & Bartlett Learning.

signs of trauma on the lower abdomen, pelvis, or perineum. There may be blood at the tip of the penis or a stain on the patient's underwear.

The presence of associated injuries or of shock will dictate the urgency of transport. In most cases,

provide prompt transport, and monitor the patient's vital signs en route.

External Male Genitalia

A few general rules apply to the treatment of injuries involving the external male genitalia:

- These injuries are very painful. Make the patient as comfortable as possible.
- Use sterile, moist compresses to cover areas that have been stripped of skin.
- Apply direct pressure with dry, sterile gauze dressings to control bleeding.
- Never move or manipulate impaled instruments or foreign bodies in the urethra.
- If possible, always identify and take avulsed parts to the hospital with the patient; label the bag with the patient's name.

If you encounter a patient with an avulsion (tearing away) of skin of the penis, wrap the penis in a soft, sterile dressing moistened with sterile saline solution, and transport the patient promptly. Use direct pressure to control any bleeding. You should try to save and preserve the avulsed skin, but do not delay treatment or transport for more than a few minutes to do so.

Managing blood loss is your top priority in amputation of the penile shaft, whether partial or complete. You should use local pressure with a sterile dressing on the remaining stump. Never apply a constricting device to the penis to control bleeding. Surgical reconstruction of even a completely amputated penis is possible if you can locate the amputated part. Wrap it in a moist, sterile dressing; place it in a plastic bag; and transport it in a cooled container without allowing it to come in direct contact with ice.

If the connective tissue surrounding the erectile tissue in the penis is severely damaged, the shaft of the penis can be fractured or severely angled, sometimes requiring surgical repair. The injury may occur during particularly active sexual intercourse. It is associated with intense pain, bleeding into the tissues, and fear. Provide prompt transport to the ED.

Accidental laceration of the skin about the head of the penis usually occurs when the penis is erect and is associated with heavy bleeding. The injury usually appears worse than it actually is; once the penis becomes flaccid, the size of the laceration decreases. Local pressure with a sterile dressing is usually sufficient to stop the hemorrhage.

It is not uncommon for the skin of the shaft of the penis or the foreskin to get caught in the zipper of pants. If a small segment of the zipper is involved (one or two teeth), you can try to unzip the pants. If a longer segment is involved or the patient is agitated, use heavy scissors to cut the zipper out of the pants to make the patient more comfortable during transport. Explain all procedures to alert patients to reduce anxiety in an already stressful situation. Be particularly careful not to cause additional injury to the scrotum while cutting the zipper away from the penis.

Urethral injuries in men are not uncommon. Lacerations of the urethra can result from straddle injuries, pelvic fractures, or penetrating wounds of the perineum. These injuries may bleed quite severely, although this may not be evident externally. Direct pressure with a dry, sterile dressing usually controls any external hemorrhage. Because the urethra is the channel for urine, it is very important to know whether the patient can urinate and whether hematuria is present. For this reason, you should save any voided urine for later examination at the hospital. Any foreign bodies that may be protruding from the urethra will have to be removed in a surgical setting.

Avulsion of the skin of the scrotum may damage the scrotal contents. If possible, preserve the avulsed skin in a moist, sterile dressing for possible use in reconstruction. Wrap the scrotal contents or the perineal area with a sterile, moist compress, and use a local pressure dressing to control bleeding. Promptly transport the patient to the ED.

Words of Wisdom

A scrotal laceration may serve as a portal through which bacteria can enter the scrotum or perineum. The resulting infection, called Fournier gangrene, causes necrosis of the muscle and other subcutaneous tissue within the scrotum. The scrotum may feel spongy, and the accumulation of gas in the scrotal sac may produce the distinctive sounds of crepitus. The scrotal tissues will become gray-black, drainage will occur at the wound site, and fever and scrotal pain will be present. This is a true emergency, and prompt transport to the hospital is indicated. If left untreated, the infection can enter the bloodstream and can be rapidly fatal.

Testicular torsion should always be suspected when there was direct trauma to the testicles and the patient has persistent pain. Transport patients with these injuries rapidly to an ED that has ultrasound capability and an available urologist.

Direct blows to the scrotum can result in the rupture of a testicle or significant accumulation of blood around the testes. In either case, you should apply an ice pack to the scrotal area while transporting the patient.

Many reports have described patients who have placed tight objects around the penis, testicles, or both. Inability to remove the object can result in incarceration of the organ, with tissue death being the most feared consequence. No attempt to remove the object should be made in the field. Instead, the patient should be transported to the hospital for

proper evaluation and treatment, which may necessitate the use of cutting devices or aspiration of the distal edema.

Female Genitalia

Lacerations, abrasions, and avulsions should be treated with moist, sterile compresses. Use local pressure to control bleeding and a diaper-type bandage to hold dressings in place. Under no circumstances should you pack or place dressings into the vagina. Leave any foreign bodies in place, and stabilize them with bandages.

Because the genitals have a rich nerve supply, injuries to them are very painful, but in general, they are not life threatening. Bleeding may be heavy, but it can usually be controlled by local compression. Contusions and other blunt injuries all require careful in-hospital evaluation. However, the urgency of the need for transport will be determined by associated injuries, the amount of hemorrhage, and the presence of shock.

If you believe your patient has been sexually assaulted, do not examine the genitalia unless obvious bleeding requires you to apply a dressing. Sexual assault is covered in detail in Chapter 25, *Gynecologic Emergencies*.

Street Smarts

Although painful, injuries to the genitalia, regardless of the patient's sex, can also be embarrassing. Treat patients with empathy and keep them covered any time you are not performing an assessment of the area or providing immediate care.

YOU are the Provider SUMMARY

1. Do you need additional resources to manage this call?

The decision to request additional resources will depend on the availability of the resources and your level of training. If you are a great distance from a trauma center and have aeromedical services available, they should also be dispatched to minimize the time to surgical care. If your ambulance is not equipped with simple extrication equipment or you do not have the necessary training to perform extrication, the fire department should be requested to perform the extrication.

2. What are the potential injuries you may encounter?

The potential injuries you may encounter will vary widely based on several factors. You may encounter a patient who is unresponsive, has multiple

fractures, has an uncontrolled airway, or has a significant internal or external hemorrhage. You should be prepared to encounter a patient with significant multisystem trauma.

3. How do you remove the branch from the wound?

Do not attempt to remove the impaled object from a wound. Using extreme caution to prevent further injury, you should have the branch cut as far away from the patient as possible (but not so far as to impair transport to the hospital), and then stabilize the branch with substantial amounts of bulky dressings and roller gauze.

4. On the basis of the patient's presentation, does she require spinal immobilization?

Absolutely. The patient hit a stationary object at a moderate rate of speed and was not wearing any

YOU are the Provider SUMMARY *continued*

protective gear. Furthermore, she has an impaled object in her abdominal cavity, which may cause further unseen injuries. Finally, the shock state she is clearly experiencing makes her unreliable from the standpoint of being able to report (based on history and physical examination findings) that she has no spinal pain, no neurologic symptoms such as numbness or tingling in her extremities, no weakness on examination of her limbs, and no tenderness along her spine. All of these criteria must be present in a reliable patient to make a determination that spinal immobilization is unnecessary.

5. Does this patient require a second IV line?

This patient is presenting with signs and symptoms of shock. On the basis of your exam findings, she has a great potential for uncontrolled internal hemorrhage. She therefore requires a second IV line. The second line should be started en route to the trauma center so as not to prolong scene time.

6. Once the tree branch is cut free from the tree, how do you secure it?

The branch should be handled with care, minimizing its movement, to avoid causing secondary injuries. Multiple bulky dressings should be applied to pad around the branch to stabilize it, and roller gauze should be applied to hold the bulky dressings in place.

7. Does this patient require evaluation at a trauma center, or should she be transported to the closest facility for evaluation first?

Because this patient presented with a penetrating injury, she requires a surgical consultation. If there is a Level I or Level II trauma center available, she should be transported there, if possible. If you do not have a local trauma center, the patient should be transported to the closest appropriate facility. As always, consult your local protocols and online medical control if you are unsure of the appropriate facility.

EMS Patient Care Report (PCR)

Date: 10-4-21	Incident No.: 20107128131	Nature of Call: ATV accident	Location: 2 miles south of Jones Road		
Dispatched: 1312	En Route: 1313	At Scene: 1324	Transport: 1344	At Hospital: 1353	In Service: 1420

Patient Information

Age: 32

EMS dispatched to unknown ATV accident 2 miles south of Jones Road on county road 55. En route, additional information received that patient struck a rock at moderate speed and is impaled on a tree branch. Pembina County Rural Volunteer Fire Department requested for extrication. On arrival, pt found lying on brush, AO × 4, ABCs intact, with an approximately 4-foot-long, 2-inch-diameter tree branch impaling her RUQ. Pt denies any injuries other than obvious tree branch. Manual stabilization established while FD cuts branch from tree. 18-gauge IV established to left antecubital area with 250-mL bolus of normal saline given. Once free from tree, branch secured with multiple bulky dressings and roller gauze. Patient secured to long backboard with +PMS to all 4 extremities. States pain 6/10. Emergency transport initiated to Legacy Hospital per trauma criteria. En route, patient vital signs improve, still reporting 6/10 pain. On arrival at ED, care and report left with MD without incident.

End of report

Prep Kit

Ready for Review

- The abdomen is divided arbitrarily into quadrants by two perpendicular lines that intersect at the umbilicus. These areas are referred to as the right upper quadrant, left upper quadrant, right lower quadrant, and left lower quadrant. The quadrant location of bruising or pain can delineate which organs are possibly involved in a traumatic injury.
- The genitourinary system is composed of the reproductive system and the urinary system. The urinary system controls the discharge of certain waste materials filtered from the blood by the kidneys. The reproductive system controls the reproductive processes from which life is created.
- Abdominal injuries can be categorized as open (penetrating trauma) or closed (blunt force trauma). Either type of injury can result in injury to the hollow or solid organs of the abdomen and cause significant life-threatening bleeding.
- Blunt force that causes closed injuries results from an object striking the body without breaking the skin, such as being hit with a baseball bat or when the patient's body strikes the steering wheel during a motor vehicle crash.
- Penetrating injuries are most frequently caused by knives or handguns. Other MOIs such as a fall on an object can also cause penetrating trauma to the abdomen.
- Blunt and penetrating trauma cause pain, although the pain may be masked at first.
- The most common sign of significant abdominal injury is tachycardia. Later signs are those of shock: decreased blood pressure and pale, cool, moist skin.
- Injury to the solid internal organs often causes significant unseen bleeding that can be life threatening.
- Injury to the hollow organs of the abdomen may cause an intense inflammatory reaction called peritonitis as caustic digestive juices leak into the peritoneal cavity. Infection may occur over as little as several hours. Peritonitis is serious and may become life threatening.
- Seat belts occasionally cause blunt injuries to the abdominal organs, and special attention should be given when evaluating patients injured in a motor vehicle with a deployed airbag.
- Injuries to the kidneys or bladder will not have obvious external signs, but there are usually more subtle clues such as lower rib pain or a possible pelvic fracture.
- Injuries to the kidneys may be difficult to detect because of the well-protected region of the

body where they are located. Be alert to bruising or a hematoma in the flank region.

- Injury to the external genitalia of male and female patients is very painful but not usually life threatening.
- Always maintain a high index of suspicion for serious intra-abdominal injury in trauma patients, particularly in a patient who exhibits signs of shock.
- To assess abdominal injuries, place the patient in a supine position, assess and record vital signs, and perform a visual inspection. Always assume that major damage has occurred to abdominal organs, even if there are no obvious signs.
- When assessing a genitourinary injury, always consider patient privacy. Be sensitive to any embarrassment, and maintain a professional presence at all times.
- Assess the abdomen for bruises or other marks that may point you toward underlying damage:

a firm abdomen, difficulty moving, abdominal tenderness and guarding, obvious entry and exit wounds, and altered vital signs.

- Treat for shock as necessary, keep the airway clear of vomitus, keep the patient warm, and promptly transport the patient to the ED or a trauma center, if available.
- Never remove an impaled object from the abdominal region. Secure it in place with a large bulky dressing, and provide prompt transport.
- Never replace an organ that protrudes from an open injury to the abdomen (evisceration). Instead, keep the organ moist and warm. Cover the injury site with a large, sterile, moist, bulky dressing.
- Establish IV access, and administer fluid at a rate to maintain systolic blood pressure greater than 80 mm Hg. Attempting to return blood pressure to normal limits may increase internal bleeding.

Vital Vocabulary

abdominal aortic aneurysm (AAA) A condition in which the walls of the aorta in the abdomen weaken and blood leaks into the layers of the vessel, causing it to bulge.

closed abdominal injury An injury in which there is soft-tissue damage inside the body but the skin remains intact.

Cullen sign A black-and-blue discoloration (ecchymosis) in the umbilical region caused by peritoneal bleeding.

evisceration The displacement of organs outside of the body.

flank The region below the rib cage and above the hip.

guarding Involuntary muscle contractions (spasm) of the abdominal wall to minimize the pain of abdominal movement and protect the inflamed abdomen; a sign of peritonitis.

hematochezia The passage of stools containing bright red blood, indicating lower gastrointestinal tract bleeding.

hematuria The presence of blood in the urine.

hemoperitoneum Collection of blood in the abdominal cavity.

hollow organs Structures through which materials pass, such as the stomach, gallbladder, small intestine, large intestine, ureters, and urinary bladder.

Kehr sign Left shoulder pain caused by blood in the peritoneal cavity due to rupture of the spleen.

melen Black, tarry, foul-smelling stools caused by digested blood that has traveled through the digestive tract; caused by upper gastrointestinal bleeding.

open abdominal injury An injury in which there is a break in the surface of the skin or mucous membrane, exposing deeper tissue to potential contamination.

peritoneal cavity The abdominal cavity.

peritonitis Inflammation of the peritoneum.

pneumoperitoneum Air in the peritoneal cavity.

rebound tenderness Pain that the patient feels when pressure is released as opposed to when pressure is applied; characteristic of appendicitis;

suggestive of a serious and potentially life-threatening condition.

scaphoid abdomen Concave abdomen (sunken abdomen or an abdomen that appears empty), which is generally the result of a ruptured diaphragm; more commonly seen in infants and children, but also seen in malnourished adults.

solid organs Solid masses of tissue where much of the chemical work of the body takes place (eg, the liver, spleen, pancreas, and kidneys).

somatic pain Localized pain, usually felt deeply, which represents irritation or injury to tissue, causing activation of peripheral nerve tracts.

supine hypotensive syndrome A drop in blood pressure caused when the heavy uterus of a supine, third-trimester–pregnant patient obstructs the vena cava, lowering blood return to the heart.

visceral pain Crampy, aching pain deep within the body, the source of which is usually difficult to pinpoint; common with genitourinary problems.

Chapter 33

Orthopaedic Injuries

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Orthopaedic Trauma

Recognition and management of

- Open fractures (pp 1541–1542)
- Closed fractures (pp 1541–1542)
- Dislocations (pp 1544–1545, 1572–1574, 1581–1582, 1584–1586)
- Amputations (pp 1546, 1589)

Pathophysiology, assessment, and management of

- Upper and lower extremity orthopaedic trauma (pp 1534–1536, 1555, 1582–1583, 1588)
- Open fractures (pp 1541–1542, 1557, 1567)

- Closed fractures (pp 1541–1542)
- Dislocations (pp 1544–1545)
- Sprains/strains (pp 1545, 1589)
- Pelvic fractures (pp 1577–1581)
- Amputations/replantation (pp 1546, 1589)
- Compartment syndrome (p 1568)

Medicine

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely ill patient.

Nontraumatic Musculoskeletal Disorders

Anatomy, physiology, pathophysiology, assessment, and management of

- Nontraumatic fractures (p 1539)

KNOWLEDGE OBJECTIVES

1. Describe the function of the musculoskeletal system. (pp 1532–1533)
2. Review the anatomy and physiology of the musculoskeletal system. (pp 1532–1538)
3. Name the four types of forces that can cause musculoskeletal injuries. (p 1540)
4. Describe the various types of musculoskeletal injuries and the signs and symptoms of each. (pp 1540–1541)
5. Differentiate between open and closed fractures. (pp 1541–1542)
6. Describe the signs and symptoms of a dislocation, sprain, and a strain. (pp 1544–1545)
7. Explain how to assess the severity of a musculoskeletal injury. (pp 1546–1547)
8. Explain the reasons for splinting at the scene versus transporting the patient immediately. (pp 1548–1549)
9. Explain the emergency medical care of a patient with an orthopaedic injury. (pp 1554–1555)
10. Explain the emergency medical care of a patient with a swollen, painful, deformed extremity (fracture). (pp 1555–1557)
11. Understand the need for splinting, including its principles and possible complications. (pp 1557–1566)

12. Describe the complications that can result from musculoskeletal injuries. (pp 1567–1570)
13. Recognize the characteristics of specific types of musculoskeletal injuries. (pp 1570–1577)
14. Explain the significance and the assessment and management of a patient with a pelvic fracture. (pp 1577–1581)
15. Explain the emergency medical care of the patient with an amputation. (p 1589)

SKILLS OBJECTIVES

1. Demonstrate the assessment of neurovascular status. (pp 1552–1553, Skill Drill 33-1)
2. Demonstrate the care of musculoskeletal injuries. (p 1556, Skill Drill 33-2)
3. Demonstrate how to apply a Hare traction splint. (pp 1560–1561, Skill Drill 33-3)
4. Demonstrate how to apply a Sager traction splint. (pp 1562–1563, Skill Drill 33-4)
5. Demonstrate how to apply a rigid splint. (p 1564, Skill Drill 33-5)
6. Demonstrate how to apply a vacuum splint. (p 1566, Skill Drill 33-6)
7. Demonstrate how to splint the clavicle, the scapula, the shoulder, the humerus, the elbow, and the forearm. (pp 1571–1576)
8. Demonstrate how to splint the hand and wrist. (p 1578, Skill Drill 33-7)
9. Demonstrate how to care for a patient with an amputation. (pp 1546, 1589)

Introduction

Musculoskeletal injuries are among the most common reasons why patients seek medical attention. Complaints related to the musculoskeletal system affect more than 126 million people in the United States, or more than one in every two adults older than 18 years.¹ More than 70% of Americans who lose workdays from health conditions report having some type of musculoskeletal impairment,² costing the US economy an estimated \$210 billion yearly in direct and indirect costs.³ These conditions are diagnosed in more women than men, and the incidence increases with age, with more than 70% of all people older than 65 years having a musculoskeletal disorder.¹

Musculoskeletal injuries are often easily identified because of pain, swelling, and deformity. Although these injuries are rarely fatal, they often result in short- or long-term disability. By providing prompt assessment and treatment, such as splinting and analgesia, advanced emergency medical technicians (AEMTs) may help reduce the disability period for patients. Despite the dramatic appearance of some musculoskeletal injuries, do not focus solely on the injury without first determining that no life-threatening injuries exist. *Never forget to assess eXsanguinating hemorrhage, Airway, Breathing, Circulation, Disability, and Exposure (XABCDEs).*

As an AEMT, you must be familiar with the basic anatomy of the musculoskeletal system. Although muscles are technically soft tissue, they are discussed in this chapter because of their close relationship with the skeleton. Therefore, the chapter begins with a review of the musculoskeletal anatomy. Various types and causes of musculoskeletal injuries in general are identified, and the assessment and treatment process for each is explained, followed by a detailed discussion of splinting. The chapter concludes with discussions on specific musculoskeletal injuries, beginning at the clavicle and ending at the feet.

Anatomy and Physiology Review

The musculoskeletal system gives the body its shape and allows for its movement. It also performs many important functions. Bones, for example, form a framework that gives the human body its shape and allows it to maintain an erect posture. *Movement* is generated because muscles are attached to bones by **tendons**. When a muscle contracts, the force generated by the muscle is transferred to a bone on the opposite side of the **joint** from the muscle, leading to motion. Bones also protect the more fragile organs and structures beneath them—for example, the skull protects the brain, the rib cage protects the

heart and lungs, and the spinal column protects the spinal cord.

Another important function of the musculoskeletal system is **hematopoiesis**—the process of generating blood cells.

Muscles

Muscles are composed of specialized cells that contract when stimulated to exert a force on a part of the body. The muscular system includes three types of muscles: cardiac, skeletal, and smooth (**FIGURE 33-1**). Skeletal muscle is also called voluntary muscle because its contractions are largely under direct voluntary control of the brain. Skeletal muscle is also striated muscle because the tissue appears striated (striped) under a microscope. By maintaining a state of partial contraction, skeletal muscle allows the body to maintain its posture and to sit or stand. Because of its high metabolic rate and demand for energy and oxygen, skeletal muscle has a rich blood supply, which causes it to bleed significantly when injured.

Muscle contraction requires energy. This energy is derived from the metabolism of glucose and results in the production of **lactic acid** (lactate). Lactic acid, in turn, must be converted into carbon dioxide (CO₂) and water, a process that requires oxygen. For this reason, vigorous muscular activity puts the body in a state of metabolic acidosis. Increasing the respiratory rate increases oxygen delivery to the tissues and increases the

FIGURE 33-1 The three types of muscles are cardiac, skeletal, and smooth.

© Jones & Bartlett Learning.

removal of CO₂ (acid) from the tissues to return the body to its normal acid-base state, represented as follows:

YOU are the Provider

Part 1

Your ambulance is assigned standby service at a local arena for a high school rodeo event. As you are watching the rodeo, you see a young man bucked off a bull; he lands on his left side. You immediately ascertain that the bull has been secured within a gated area and that the scene is now safe for you to enter. On arriving at the patient's side, you note he is alert and oriented and in moderate distress. You see an obvious deformity of the left femur in the midshaft area, and a possibly unstable pelvis. Per your protocols, you ask your partner to contact dispatch and request the local flight service as you continue to assess the patient. As a precaution, you place the patient on a nonrebreathing mask and administer oxygen at 15 L/min. On completion of your primary survey, your partner informs you there are no helicopter or paramedic units available.

1. How should you prepare this patient for transport?
2. What should you do when advanced modes of transport are not available?

Muscle Innervation

Skeletal muscle is innervated by somatic motor neurons that transmit electrical stimuli to a muscle that cause it to contract. The combination of the muscle and the neuron that innervates it constitutes a motor unit. A motor unit that receives a signal to contract responds as forcefully as possible or does not contract at all: it is an all-or-nothing response. To generate a more forceful contraction, more neurons need to signal more muscle cells to contract, a process called recruitment.

Musculoskeletal Blood Supply

Skeletal muscle is supplied with arteries, veins, and nerves. Disease or trauma can result in the loss of a muscle's nerve supply; this, in turn, can lead to weakness and eventually atrophy, or a decrease in the size of the muscle and its inherent ability to function.

When a person has a musculoskeletal injury, the arteries that supply the injured region may also be damaged. Therefore, it is important to realize which arteries (and corresponding veins) are present in each part of the extremity (**FIGURE 33-2**).

The blood supply in each upper extremity originates from the subclavian artery. When the subclavian artery reaches the axilla, it is referred to as the axillary artery. After giving off several branches that supply the shoulder region with blood, the artery leaves the axilla and becomes the brachial artery. After it passes through the elbow, the brachial artery divides into the radial artery and ulnar artery. In the hand, the radial and ulnar arteries form superficial and deep arcades of blood vessels that branch to form the arteries of each finger, the digital arteries.

In the lower extremities, the blood supply originates from the external iliac arteries. When the external iliac artery reaches the leg, it becomes the femoral artery. When it reaches the knee, the femoral artery turns medially and posteriorly and is referred to as the popliteal artery. The popliteal artery divides into the peroneal artery, the anterior tibial artery, and the posterior tibial artery. The anterior tibial artery travels along the anterior and lateral surface of the tibia until it reaches the ankle, where it proceeds along the dorsal surface of the foot toward the great toe and becomes the dorsalis pedis

FIGURE 33-2 The arterial supply of the extremities. **A.** Upper extremity. **B.** Lower extremity.

FIGURE 33-3 The pectoral girdle. **A.** Anterior view, including the clavicle. **B.** Posterior view, including the scapula.

© Jones & Bartlett Learning.

artery. The posterior tibial artery travels along the posterior aspect of the tibia until it reaches the ankle, where it follows a path just behind the medial malleolus until it reaches the plantar aspect of the foot. The peroneal artery branches off of the posterior tibial artery and supplies the posterior and lateral components of the leg. Within the foot, arcades of arteries supply the various structures with blood and give off branches that form the digital arteries of the toes.

The Skeleton

The skeleton, which gives us our recognizable human form, protects our vital internal organs, and allows us to move, is made up of approximately 206 bones. It may be divided into two distinct portions: the **axial skeleton** and the **appendicular skeleton**.

The axial skeleton comprises the bones of the central part, or axis, of the body; its divisions include the vertebral column, skull, ribs, and sternum.

The appendicular skeleton is divided into the pectoral girdle, the pelvic girdle, and the bones of the upper and lower extremities. The pectoral girdle (shoulder girdle) consists of two scapulae and two clavicles (**FIGURE 33-3**). The clavicles act as struts to keep the shoulder propped up; however, because they are both slender and very exposed, these bones are vulnerable to injury.

The upper extremity extends from the shoulder to the fingertips and is composed of the upper arm (humerus), elbow, and forearm (**FIGURE 33-4**). The radius and ulna make up the forearm. Because

FIGURE 33-4 The anatomy of the arm.

© Jones & Bartlett Learning.

these bones are arranged in parallel, when one is broken, the other is often broken as well.

The hand contains three sets of bones: wrist bones (carpals), hand bones (metacarpals), and finger bones (phalanges) (**FIGURE 33-5**). The carpals, especially the scaphoid, are vulnerable to fracture when a person falls on an outstretched hand. Phalanges are more apt to be injured by a crush injury, such as being slammed in a car door.

The pelvis supports the body weight and protects the structures within the pelvis: the urinary bladder, rectum, and female reproductive organs.

The pelvic girdle consists of three separate bones—the ischium, ilium, and pubis—fused together to form the innominate (or hip) bone (**FIGURE 33-6**). The two iliac bones are joined posteriorly by tough ligaments to the sacrum at the sacroiliac joints; the two pubic bones are connected anteriorly by equally tough ligaments at the pubic symphysis.

FIGURE 33-5 The anatomy of the wrist and hand.

© Jones & Bartlett Learning.

These joints allow very little motion, so the pelvic ring is strong and stable.

Each lower extremity consists of the bones of the thigh, leg, and foot (**FIGURE 33-7**). The femur (thigh bone) is a long, powerful bone that connects in the ball-and-socket joint of the pelvis and in the hinge joint of the knee. The femoral head is the ball-shaped part that fits into the acetabulum. It is connected to the shaft (diaphysis) of the femur by the femoral neck. The femoral neck is a common site for fractures, generally referred to as hip fractures, especially in the older adult population.

The lower leg consists of two bones, the tibia and the fibula. The tibia is vulnerable to direct blows and can be felt just beneath the skin. The fibula is an attachment point for the lateral ligaments of the knee joint; it also serves as the lateral stabilizer of the ankle joint (lateral malleolus) at its distal **articulation**.

The foot consists of three classes of bones: ankle bones (tarsals), foot bones (metatarsals), and toe bones (phalanges) (**FIGURE 33-8**). The largest of the tarsal bones is the heel bone (calcaneus), which is subject to injury with axial loading injuries, such as when a person jumps from a height and lands on the feet.

A joint is formed wherever two bones come into contact. The sternoclavicular joint, for example, is

FIGURE 33-6 The pelvic girdle.

© Jones & Bartlett Learning.

FIGURE 33-7 The bones of the thigh, leg, and foot.

© Jones & Bartlett Learning.

where the sternum and the clavicle come together. Joints are held together in a tough fibrous structure known as a capsule and are bathed and lubricated by synovial fluid. The various motions that a joint may allow include flexion, extension, **abduction**, **adduction**, rotation, circumduction, pronation, and supination (**FIGURE 33-9**).

Bone Classifications

Bones are classified based on their shapes. *Long bones* are longer than they are wide; examples include the femur, humerus, tibia, fibula, clavicle, phalanges, radius, and ulna. *Short bones* are nearly as wide as they are long; they include the metacarpals and metatarsals. *Flat bones* are thin, broad bones; they include the sternum, ribs, scapulae, and cranial bones. *Irregular bones* have complex shapes

FIGURE 33-8 The bones of the foot and ankle.

© Jones & Bartlett Learning.

FIGURE 33-9 Joints in the body.

© Jones & Bartlett Learning.

that are designed to perform specific functions, such as the bones of the vertebrae and the mandible. Sesamoid bones, or *round bones*, are generally found in tendons. The patella is the largest of the sesamoid bones.

Typical Long Bone Architecture

Long bones have several distinct regions and anatomic features (**FIGURE 33-10**). These bones can grow to such lengths because of the presence of the growth plate, or **physis**, in children. Once a person reaches adulthood, the growth plate closes and the mature adult bone is complete. The long bone is divided into three regions: the diaphysis, the epiphyses, and the metaphyses.

The area where two bones come in contact to form a joint is covered by a thin layer of articular cartilage, a smooth, pearly white substance that acts as a cushion to protect the bones from damage and wear and allows the ends of the bones to easily glide over each other. The portion of bone that is not covered by articular cartilage is, instead, covered by the periosteum. This dense, fibrous membrane contains capillaries and cells that are important for bone repair and maintenance.

In the inner portion of the long bone, blood comes from the nutrient artery of the bone. Once it penetrates the bone's outer cortex, the artery enters

the medullary canal, the hollow inner portion of the shaft that is lined by the endosteum and contains yellow (fatty) marrow in adults.

Tendons, Ligaments, and Cartilage

A tendon connects skeletal muscle to bone. These flat or cordlike bands of connective tissue are white and have a glistening appearance. Tendons cross joints to create a pulling force between two bones when a muscle contracts.

A **ligament** connects bone to bone and helps maintain the stability of joints and determine the degree of joint motion. These inelastic bands of connective tissue have a structure similar to tendons.

Cartilage consists of fibers of collagen embedded in a gelatinous substance. This flexible connective tissue forms the smooth surface over bone ends where they articulate, provides cushioning between vertebrae, gives structure to the nose and external ear, forms the framework of the larynx and trachea, and serves as the model for the formation of the skeleton in children. Cartilage has a very limited vascular supply, and it does not heal if it is injured.

Age-Associated Changes

The musculoskeletal system, like any body system, is affected by aging. Bones age as do other tissues of the body, decreasing in density after the age of 35 years. This trend leads to a loss of height and produces changes in facial structure. In women, the decrease in bone density accelerates once menopause is reached because of the loss of estrogen, a hormone that helps promote bone formation. A significant decrease in bone density, called **osteoporosis** (**FIGURE 33-11**), is associated with a higher risk of fracture. People with osteoporosis are at increased risk for incurring fractures, especially in the hip, spine, and wrist.

FIGURE 33-10 Anatomy of the long bone. **A.** The humerus. Notice the long shaft and dilated ends. **B.** Longitudinal section of the humerus showing compact bone, spongy bone, and marrow.

© Jones & Bartlett Learning.

Special Populations

A large portion of the older adult population has joint pain that ranges from mild to debilitating. As the body ages, wear and tear creates injury and causes inflammation of the joints, resulting in arthritis, bursitis, and a host of other medical conditions.

A

B

FIGURE 33-11 The structural difference between normal and osteoporotic bone. **A.** Normal bone in a 29-year-old woman. **B.** Osteoporotic bone in a 92-year-old woman.

© Courtesy of the International Osteoporosis Foundation.

Aging of muscles, cartilage, and other connective tissues may also lead to degradation of joints and disk herniation. For example, the water content of the intervertebral disks decreases as a person ages, increasing the risk of disk herniation. In some joints, the cartilage may become degraded, leading to arthritis and pain; in others, the cartilage becomes calcified, leading to restricted motion. For more information about musculoskeletal differences associated with age, see Chapter 36, *Pediatric Emergencies*, and Chapter 37, *Geriatric Emergencies*.

Special Populations

Splinting an injured extremity (eg, a fractured forearm) is most optimally performed with the extremity in a straightened position. In some older adult patients, straightening the injured extremity may not be possible and may cause further injury. This is particularly true in patients with arthritis: a degenerative condition that causes a reduced range of motion in the joints. If, while attempting to straighten the extremity, the patient experiences increasing joint pain or you feel resistance, stop and splint the injured limb in the position in which it is resting.

Pathophysiology

Musculoskeletal injuries may result from both blunt and penetrating trauma. Sports injuries account for a significant number of musculoskeletal injuries in the United States each year, particularly among children and young adults age 20 years and younger.⁴ Other common causes of these injuries include motor vehicle crashes (MVCs) and falls. Among children, intentional trauma or abuse is a common cause of fractures and musculoskeletal injuries, with one-third to one-half of all abused children experiencing fractures.⁵

In some cases, a force that might not generally cause harm to normal healthy bone produces a fracture. Such a **pathologic fracture** occurs when a medical condition (eg, metastatic cancer) causes the bone to become abnormally weak; a fracture may then occur with even minimal force. Older adults, particularly those with osteoporosis, have weaker, more brittle bones, which leaves them more susceptible to fractures than are younger people.

Words of Wisdom

Assessment and treatment of pathologic fracture (also called nontraumatic fracture) are the same as with any fracture, but require special consideration given the patient's history. Apply gentle force when manipulating a fracture so you do not create more harm in an already weakened area, and pad the area as needed for comfort and support. Document the patient history and ensure you include the presence or absence of any injury preceding the event.

Special Populations

Osteogenesis imperfecta, or brittle bone disease, makes people more prone to pathologic fractures. Fractures may occur from something as simple as lifting a child or leaning onto an outstretched arm. Use extreme care when handling these patients, because the most minute force may cause concomitant injury or fractures. Stress the patient history when communicating with the receiving facility.

Mechanism of Injury

Significant force is generally required to cause fractures and dislocations. This force may be applied to a limb in any of the following ways:

- Direct blows
- Indirect forces
- Twisting forces
- High-energy injuries

Words of Wisdom

Injury to bones and joints is often associated with injury to the surrounding soft tissues, especially to the adjacent nerves and blood vessels. The entire affected area is known as the **zone of injury** (FIGURE 33-12). Depending on the amount of kinetic energy that the tissues absorb from forces acting on the body, this zone may extend to a distant point. For this reason, do not be distracted by a patient's obvious injury; you must first complete a primary survey to check for life-threatening injuries. This is especially true when assessing damage from high-energy trauma.

FIGURE 33-12 The zone of injury is the area of soft tissue, including the adjacent nerves and blood vessels, that surround the obvious injury of a bone or joint.

© Jones & Bartlett Learning.

A direct blow fractures the bone at the point of impact. Penetrating injuries may also lead to a fracture or other musculoskeletal injury. A high-velocity injury, such as that caused by a high-power rifle, typically shatters bone and causes extensive soft-tissue damage. An impalement injury commonly causes a soft-tissue injury similar to that seen in a low-velocity penetrating injury. If the impaled object happens to strike a bone, it may cause a fracture. In any case of impalement, it is essential to stabilize the object to protect the soft tissues from further injury.

An **indirect injury** occurs when force is applied to one region of the body but causes an injury (eg, fracture, dislocation) in another region of the body. In this type of injury, the force is transmitted through the skeleton until, at some point, it reaches an area that is structurally weak in comparison with the other parts of the musculoskeletal system through which the force has traveled. For example, a hip fracture may occur when a person's knee strikes the dashboard during an MVC. In this case, the force is applied to the knee and travels proximally along the femur. When this force reaches the femoral neck, it causes the femoral neck to fracture.

Forces may be transmitted along the entire length of a bone or through several bones in series, and may cause an injury anywhere along the way. Thus, a person falling on an outstretched hand may have one or more injuries as the result of forces transmitted proximally from the point of impact: (1) fracture of the scaphoid bone of the hand (direct blow), (2) fracture of the distal ulna and radius, (3) fracture-dislocation of the elbow, (4) fracture-dislocation of the shoulder, or (5) fracture of the clavicle. When you are caring for patients who have fallen, immediately identify the point of contact and the mechanism of injury (MOI) so you decrease the chance of overlooking any associated injuries.

Twisting forces are a common cause of musculoskeletal injury and can result in fractures, sprains, and dislocations. These kinds of injuries are common in football and skiing. Typically, the distal part of the limb remains fixed, as when cleats or a ski holds the foot to the ground, while torsion develops in the proximal section of the limb; the resulting force causes tearing of tendons and ligaments and fractures of bone.

Some injuries are commonly encountered together because of the way the causative forces are

TABLE 33-1 Musculoskeletal Injuries That Commonly Occur Together

If You Find	Look For
Scapular fracture	Rib fracture, pulmonary contusions, pneumothorax
Scaphoid fracture	Wrist, elbow, or shoulder fracture
Pelvic fracture	Lumbosacral spine and other long bone fractures, intra-abdominal or genitourinary injury
Hip dislocation	Fracture of the acetabulum or femoral head
Femoral fracture	Dislocation of ipsilateral hip
Patellar fracture	Fracture-dislocation of ipsilateral hip
Knee dislocation	Tibial fracture; distal pulse may be absent
Calcaneal fracture	Fracture of the ankle, leg, hip, pelvis, spine, and the other calcaneus

© Jones & Bartlett Learning.

transmitted; thus, if you find one, look for the others (**TABLE 33-1**). Pain and swelling over the scaphoid (navicular) bone of the wrist, for example, means the patient fell hard against an outstretched hand, so the patient may have other injuries anywhere along the axis from the hand to the shoulder.

Fractures

A **fracture** is a broken bone. More precisely, it is a break in the continuity of a bone. Fractures occur when the magnitude of the force applied to a bone (a single application or an accumulation of repetitive applications) overcomes the strength of the bone. The strength of a bone may be affected by age, osteoporosis, nutritional status, and disease processes.

Types of Fractures

Fractures are classified as either open or closed. In an **open fracture**, sometimes called a compound fracture, a break in the overlying skin allows the fracture to be exposed to the outside environment (**FIGURE 33-13**). In addition to having a higher risk

**FIGURE 33-13** An open fracture.

© Courtesy of Rhonda Hunt.

**FIGURE 33-14** A closed fracture.

© Courtesy of Rhonda Hunt.

of infection, open fractures have the potential for more blood loss than a closed fracture.

In a **closed fracture**, the skin over the fracture site remains intact (**FIGURE 33-14**). The increased interstitial pressure within the hematoma compresses the blood vessels, limiting the size of the hematoma. In a closed femur fracture, the blood loss may exceed 1 L before enough pressure develops to tamponade the bleeding. In contrast, open fractures allow much of the blood to escape, so tamponade does not occur as readily or at all.

Determining whether a fracture is open or closed is not always as easy as it sounds. With an open fracture, there is an external wound, caused either by the same blow that fractured the bone or

by the broken bone ends lacerating the skin. The wound may vary in size from a very small puncture to a gaping tear that exposes bone and soft tissue. When you assess and treat patients with possible fractures or dislocations, determine whether the overlying skin is damaged. Regardless of the extent and severity of the damage to the skin, you should treat any injury that breaks the skin as a possible open fracture. Significant blood loss and a higher likelihood of infection are complications that you must try to limit; these tend to occur with open fractures.

Words of Wisdom

Lacerations can extend through skin and subcutaneous tissue, and even into the underlying muscles and adjacent nerves and blood vessels. The presence of lacerations may also be a sign of an underlying fracture.

Fractures are also described by whether the bone is moved from its normal position. **Angulation** of a fracture means that the bone is misaligned as a result of the injury and that an angle has formed between the fractured fragments. Angulation may occur in the frontal plane, sagittal plane, or both. A **nondisplaced fracture** (also known as a hairline fracture) is a simple crack of the bone that may be difficult to distinguish from a sprain or simple contusion. Radiographic examinations are required for physicians to diagnose any type of fracture, particularly a nondisplaced fracture. In a **displaced fracture** the two bone ends at the fracture are separated in at least one plane and may produce actual deformity, or distortion, of the limb by shortening, rotating, or angulating it. Often, the deformity is obvious and can be associated with crepitus. However, in some cases the deformity is minimal. Ensure you look for differences between the injured limb and the opposite uninjured limb in any patient with a suspected fracture of an extremity (**FIGURE 33-15**).

Medical personnel often use the following special terms to describe types of fractures (**FIGURE 33-16**):

- **Transverse.** A fracture that occurs straight across the bone. This is usually the result of a direct blow injury.

FIGURE 33-15 Always compare the injured limb with the uninjured limb when checking for deformity.

© American Academy of Orthopaedic Surgeons.

FIGURE 33-16 Types of fractures. **A.** Transverse fracture of the tibia. **B.** Oblique fracture of the humerus. **C.** Spiral fracture of the femur. **D.** Comminuted fracture of the tibia. **E.** Greenstick fracture of the fibula. **F.** Compression fracture of a vertebral body.

© Jones & Bartlett Learning.

- **Oblique.** A fracture in which the bone is broken at an angle across the bone. This is usually the result of a sharp, angled blow to the bone.
- **Spiral.** A fracture caused by a twisting or spinning force, causing a long, spiral-shaped break in the bone. This is sometimes the result of abuse in young children.
- **Comminuted.** A fracture in which the bone is broken into more than two fragments.
- **Greenstick.** An incomplete fracture that passes only partway through the shaft of a bone but may still cause substantial angulation; occurs in children.
- **Incomplete.** A fracture that does not run completely through the bone; a nondisplaced partial crack.

- **Pathologic.** A fracture of weakened or diseased bone, seen in patients with osteoporosis, infection, or cancer; often produced by minimal force.
- **Epiphyseal.** A fracture that occurs within the growth plate of a child's bone and may lead to growth abnormalities.

Signs and Symptoms of a Fracture

The primary symptom of a fracture is *pain* that is usually well localized to the fracture site. In addition, the patient may report hearing a snap or feeling a break. Signs of fracture detected on physical examination include the following:

- *Deformity* is one of the most reliable signs of a fracture. The limb may be found in an unnatural position or show motion at a place where there is no joint. Compare the deformed limb with the extremity on the other side (**FIGURE 33-17**).
- *Shortening* occurs in fractures when the broken ends of a bone override each other. It is characteristic of femur fractures, for example, because the broken femur can no longer serve as a strut to oppose spasm in the powerful thigh muscles.
- Visual inspection will usually reveal *swelling* at the fracture site due to bleeding from the broken bone and the accumulation of fluid (**FIGURE 33-18**). If swelling is severe, it may mask deformity of the limb. Generalized swelling may occur several hours after injury.
- As blood infiltrates the tissues around the broken bone ends, *bruising* will become apparent

FIGURE 33-17 Obvious deformity should increase your index of suspicion for a fracture.

© Charles Stewart MD, EMDM, MPH.

(**FIGURE 33-19**). Fractures are very often associated with **ecchymosis** (discoloration) of the surrounding soft tissues. Bruising may be present after almost any injury; it is not specific for bone or joint injuries.

- A fractured bone is almost invariably *tender to palpation* over the fracture site. **Point tenderness** is tenderness that is sharply localized at the site of injury, found by gently palpating along the bone with the tip of one finger.

FIGURE 33-18 Swelling around an ankle from an injury. It is often not possible without radiographic imaging to determine whether a patient has a fracture or not.

© fotokostic/iStock/Getty Images.

FIGURE 33-19 Fractures almost always have associated bruising into the surrounding soft tissue.

© Jane Shemilt/Science Source.

- *Pain*, along with tenderness and bruising, commonly occurs in association with fractures. Occasionally, nondisplaced fractures are not very painful, and there is minimal soft-tissue damage.
- *Guarding* and *loss of use* characterize most fractures. Guarding occurs when the muscles around the fracture contract to prevent any movement of the broken bone. Guarding is also used to describe behavior of the patient to protect the injury against movement and further discomfort. Guarding does not occur with all fractures; some patients may continue to use the injured part for some time. An inability to use the extremity is the patient's way of immobilizing it to minimize pain. The patient will try to keep a fractured bone still and will avoid putting any stress on it. Sometimes the measures a patient takes to protect a fractured bone from movement are so characteristic that you can almost know the type of fracture without examining the extremity. A patient who walks to the ambulance holding the dorsum of one wrist in the other hand, for example, very often has a fracture of the distal radius. A patient standing with the head cocked toward a "knocked-down shoulder" probably has a fracture of the clavicle on the side to which the head is leaning.
- Palpation may reveal **crepitus**, a grating sensation, over the broken bone ends. Crepitus may be noted as an incidental finding during splinting attempts. Do *not* try to elicit this sign, because your efforts may result in further injury to the bone and surrounding soft tissues, and severe pain.
- Also called free movement, *false motion* occurs at a point in the limb where there is no joint. It is a positive indication of a fracture.
- A *locked joint* (a joint that is locked into position) is difficult and painful to move.
- In an open fracture, *exposed bone ends* may be visible in the wound (FIGURE 33-20).

Words of Wisdom

Point tenderness is the most reliable indicator of an underlying fracture.

FIGURE 33-20 Bone ends may protrude through the skin or be visible within the wound of an open fracture.

© Charles Stewart MD, EMDM, MPH.

Dislocations

When bones are forced beyond their normal limits, the bones that form a joint may break, or they may become displaced and the supporting ligaments and joint capsule may tear. In a **dislocation**, a bone is totally displaced from the joint. Typically, at least part of the supporting joint capsule and some of the joint's ligaments are disrupted. Dislocations occur when a body part moves beyond its normal range of motion. The dislocated bones become locked in place by muscle spasms. Evaluate the patient for obvious and significant deformity, a significant decrease in the joint's range of motion, and severe pain. In all cases of a dislocation, you should suspect a fracture until it is ruled out by radiographs.

A dislocated joint may spontaneously undergo **reduction**, or return to its normal position, before you begin your assessment. In this situation, you may suspect a dislocation based on the patient history. Often, however, the joint surfaces remain completely separated from each other. A dislocation that does not spontaneously reduce is a serious problem: the ends of the bone can become locked in a displaced position, making any attempt at motion of the joint very difficult and painful.

The partial dislocation of a joint is known as a **subluxation**. In this type of injury, the articular surfaces of the bones that form the joint are no longer completely in contact. In some cases, part of the joint capsule and supporting ligaments may be damaged. Despite the subluxation, the patient may be able to move the joint to some degree. Failure to

FIGURE 33-21 Joint dislocations, such as in this finger, are characterized by deformity, swelling, pain with any movement, tenderness, locking, and impaired circulation.

© Dr. P. Marazzi/Science Source.

recognize and treat a subluxation may lead to persistent joint instability and pain.

The signs and symptoms of a dislocated joint are similar to those of a fracture (**FIGURE 33-21**):

- Marked deformity
- Swelling
- Pain that is aggravated by any attempt at movement
- Tenderness on palpation
- Virtually complete loss of normal joint motion (locked joint)
- Numbness or impaired circulation to the limb or digit

Words of Wisdom

The principal sign of a dislocation is deformity. Symptoms may include pain, a feeling of pressure over the involved joint, and a loss of motion of the joint (ie, the joint seems “frozen”). Patients with a posterior dislocation of the shoulder, for example, are unable to raise their arm, so they hold it against their side instead.

A dislocation is considered an urgent injury because of its potential to cause **neurovascular compromise** distal to the site of injury. If the dislocated bone presses on a nerve, the patient may experience numbness or weakness distally; if an artery is compressed, distal pulses may be absent (such as in a knee dislocation). For these reasons, you should always assess the patient’s neurovascular status distal to the site of dislocation (check

pulse and motor and sensory function) prior to as well as after splinting.

Sprains

A **sprain** is an injury in which ligaments are stretched or torn. It usually results from a sudden movement of a joint beyond its normal range of motion, accompanied by a temporary subluxation. Most sprains involve the ankle or the knee; most of these injuries occur after a person misjudges a step or landing. Evasive moves, such as those performed during sporting events, commonly cause sprains in athletes. The following signs and symptoms may indicate a patient has a sprain:

- Point tenderness can be elicited over the injured ligaments.
- Swelling and ecchymosis appear at the point of injury to the ligament resulting from torn blood vessels.
- Pain causes the patient to be unwilling to move or use the limb normally.
- Instability of the joint is indicated by increased motion, especially at the knee; however, this may be masked by severe swelling and guarding.

In contrast to fractures and dislocations, sprains rarely involve deformity. In these injuries, joint mobility is usually limited by pain, not by joint incongruity.

Strains

A **strain** (pulled muscle) is an injury to a muscle and/or tendon that results from a violent muscle contraction or from excessive stretching. Patients typically report an immediate sharp pain and the sound of a “snap” when the muscle tears. Often no deformity is present, and only minor swelling may be noted at the site of injury, along with severe muscle weakness. Some patients may report extreme point tenderness and increased pain with passive movement of the injured extremity. The general treatment of strains is similar to field management for sprains, dislocations, and fractures.

Achilles Tendon Rupture

A rupture of the Achilles tendon usually occurs in athletes older than 30 years who are involved in start-and-stop sports such as basketball or football. Recent use of certain types of antibiotics may

FIGURE 33-22 An amputation involving a leg.

Courtesy of Andrew N. Pollak, MD, FAAOS.

also predispose patients to these injuries. The most immediate indications are pain from the heel to the calf and a sudden inability to perform **plantar flexion** of the foot. As time passes, the calf muscles begin to contract proximally and a deformity within the calf may develop. Acute management of an Achilles tendon injury includes RICE—Rest, Ice, Compression, and Elevation—and pain control. Long-term treatment may involve splinting or surgery.

Amputations

An **amputation** is the separation of a limb or other body part from the remainder of the body (**FIGURE 33-22**). The amputation may be incomplete, leaving only a small segment of tissue connecting the part, or it may be complete, causing the part to be fully separated. Hemorrhage from complete or incomplete amputations can be severe and life threatening. Fractures may also be present with amputations.

Words of Wisdom

Focus on the patient, not the amputation. Stabilizing and transporting the patient are more important than caring for the amputated part.

Patient Assessment

As an AEMT, your assessments, attempts to splint, and work to stabilize the patient's condition are very important. However, when you are assessing

an injured patient, *do not become distracted by visually impressive injuries!* It is essential to complete the primary survey of the patient to determine and address life threats before focusing on the extremities. Always carefully assess the MOI to try to determine the amount of kinetic energy that an injured limb has absorbed, and maintain a high index of suspicion for associated injuries. Other priorities should include identifying the injuries, preventing further harm or damage to the injured structures and surrounding tissues, supporting the injured area, and administering pain medication if necessary.

In cases of musculoskeletal injuries, patients may be classified based on the presence or absence of associated injuries:

- Life- or limb-threatening injury or condition, including life- or limb-threatening musculoskeletal trauma
- Life-threatening injuries and only simple musculoskeletal trauma
- Life- or limb-threatening musculoskeletal trauma and no other life-threatening injuries
- Isolated, non-life-threatening or non-limb-threatening injuries

You must become skilled at quickly and accurately assessing the severity of injury. The Golden Hour (or initial Golden Period) is critical not only for maintaining life, but also for preserving limbs. In an extremity with anything less than complete circulation, prolonged hypoperfusion can cause significant damage. For this reason, any suspected open fracture or vascular injury is considered a medical emergency, especially in a patient with multiple traumatic injuries.

Remember that most injuries are not critical; you can identify critical injuries by using the musculoskeletal injury grading system shown in **TABLE 33-2**.

Scene Size-up

Information from dispatch may indicate the MOI, the number of patients involved, and any first aid procedures used prior to your arrival. This will be useful information for you to think about as you travel to the scene. Remember that the information given by the dispatcher is only as accurate as the patient's or bystander's report. In addition, the situation may change prior to your arrival at the incident.

TABLE 33-2 Musculoskeletal Injury Grading System

Minor injuries	• Minor sprains • Fractures or dislocations of digits
Moderate injuries	• Open fractures of digits • Nondisplaced long bone fractures • Nondisplaced pelvic fractures • Major sprains of a major joint
Serious injuries	• Displaced long bone fractures • Multiple hand and foot fractures • Open long bone fractures • Displaced pelvic fractures • Dislocations of major joints • Multiple digit amputations • Laceration of major nerves or blood vessels
Severe, life-threatening injuries (survival is probable)	• Multiple closed fractures • Limb amputations • Fractures of both long bones of the legs (bilateral femur fractures)
Critical injuries (survival is uncertain)	• Multiple open fractures of the limbs • Suspected pelvic fractures with hemodynamic instability

© Jones & Bartlett Learning.

As you arrive at the scene, observe the area for hazards. Try to identify the forces associated with the MOI. A mask, gown, and eye protection may be needed for incidents involving severe MOIs or when there is the possibility of hidden bleeding. Evaluate the need for law enforcement support, paramedic backup, or additional ambulances, and request assistance early based on your initial scene assessment.

As you observe the scene, look for indicators of the MOI. When you are assessing a patient who has experienced a significant MOI, be alert for both primary and secondary injuries. Primary injuries are a result of the MOI, whereas secondary injuries are the result of what happens after the initial injury. For example, a pedestrian who is hit by a motor vehicle may experience a primary pelvic injury, but a secondary head injury may occur when the patient rolls onto the hood of the motor vehicle.

Safety

The first step for any assessment is to ensure scene safety, use personal protective equipment, and take standard precautions!

YOU are the Provider

Part 2

You ask your partner to retrieve the pelvic splints and spinal immobilization equipment from the ambulance while you continue to question the patient. The patient states that he remembers the entire incident and just wishes that you could “knock him out.” When your partner returns with the equipment, you apply a cervical collar to the patient, then gently slide the pelvic splint underneath the patient and cinch it to the appropriate size. As you secure the splint, the patient breathes a sign of relief, saying that the pain feels a little better now. You and your partner gently place the patient onto a long backboard, move him onto your stretcher, and wheel him to the ambulance. Once the patient is in your ambulance, you establish one intravenous (IV) line and initiate a 250-mL normal saline bolus due to his circulatory status.

Recording Time: 1 Minute

Appearance	Responsive
Level of consciousness	Alert and oriented
Airway	Patent
Breathing	22 breaths/min, nonlabored
Circulation	Cool, clammy

3. What is the potential blood loss in a femur fracture? Pelvic fracture?
4. Should this patient have a second IV line initiated?

Primary Survey

Perform a primary survey by focusing on the patient's mental status, XABCDEs, and priority. If the primary survey indicates the patient has no immediate life-threatening condition and only localized musculoskeletal trauma, then continue with history taking and a secondary assessment. If the patient has a significant MOI, then complete a rapid full-body scan on scene, and then perform a full-body exam en route to the emergency department (ED). The priorities throughout the assessment and management of musculoskeletal injuries should be to identify the injuries, prevent further harm or damage to the injured structures and surrounding tissues, and support the injured areas.

Evaluate the patient's level of consciousness and orientation. Check for responsiveness using the AVPU scale (Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive). Generally, you can assess patients' mental status by asking them about their chief complaint. If patients are alert, the information they provide should help direct you to any apparent life threats. If they are not alert, determine whether they respond to verbal or painful stimuli or whether they are unresponsive. An unresponsive patient may indicate a life-threatening condition. Administer oxygen as needed via a nonrebreathing mask (or a bag-mask device, if indicated) to all patients whose level of consciousness is less than alert and oriented, and provide immediate transport to the ED.

Perform a rapid full-body scan of the patient, and ask about the MOI. Was it a direct blow, indirect force, twisting force, or high-energy injury? In many situations, the musculoskeletal complaints will be simple and usually not life threatening. In other situations, such as those with a significant MOI, patients may complain of multiple problems, only one of which involves a musculoskeletal injury. The initial interaction with the patient will provide you with a starting point and help you to distinguish simple conditions from complex injuries. If the patient was subjected to significant trauma and multiple body systems are affected, the musculoskeletal injuries may be a lower priority. Do not waste scene time on prolonged musculoskeletal assessment or splinting in such a case.

Fractures and sprains usually do not create airway and breathing conditions. Other problems,

such as injuries to the head, intoxication, or other related illnesses and injuries, may cause inadequate breathing. Evaluate the chief complaint and MOI to help you identify whether the patient has an open airway and whether breathing is present and adequate. In a responsive patient, this step is as simple as noting whether the patient can speak normally. In an unresponsive patient, it is as simple as opening the airway to check for breathing. If a spinal injury is suspected, take the appropriate precautions and prepare for stabilization. Address musculoskeletal injuries first if there is profuse bleeding; however, even then, direct another provider if available to control bleeding while you assess the airway. Address exsanguinating hemorrhage first; very quickly afterwards, address airway and breathing concerns.

Words of Wisdom

Be mindful of scene time. Use a long backboard as a "full-body splint" in place of multiple individual splints and complete additional assessment and treatment of musculoskeletal injuries during transport.

Your circulatory assessment should focus on determining whether the patient has a pulse, has adequate perfusion, or is bleeding. If the patient is alert, as are most patients with fractures and dislocations, the patient will have a pulse. If the patient is unresponsive, check for a pulse by palpating the carotid artery. Hypoperfusion (shock) and bleeding problems will most likely be your primary concern. If the skin is pale, cool, or clammy and capillary refill time is slow, treat the patient for shock immediately. Maintain a normal body temperature and improve perfusion by administering oxygen. If musculoskeletal injuries in the extremities are suspected, at least initially stabilize them (or splint them) before you move the patient. Eliminating such injuries as a potential cause of shock may need to be done later in your assessment. Assess for pulses proximal to the injury and note any circulatory changes before and after any manipulation as well as frequently during transport.

Fractures can break through the skin and cause external bleeding. This rupture may occur either during the initial injury or during manipulation of the extremity while preparing for splinting or transport. Careful handling of the extremity

FIGURE 33-23 Control external bleeding with direct pressure. If this technique is not effective, apply a tourniquet.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

minimizes this risk. If external bleeding is present, bandage the extremity quickly to control bleeding (**FIGURE 33-23**). Use sterile dressings to cover the wound and bone to reduce the potential for bone infection. The bandage should be secure enough to control bleeding without restricting circulation distal to the injury. Monitor bandage tightness by assessing the pulse, sensation, and movement distal to the bandage. Swelling from fractures and internal bleeding may cause bandages to become too tight. If bleeding cannot be controlled, then quickly apply a tourniquet.

If the patient has an airway or breathing condition, or significant bleeding, provide rapid transport to the closest hospital for treatment. A patient who has a significant MOI but whose condition appears otherwise stable should also be transported promptly to the closest, most-appropriate hospital. Patients with bilateral fractures of the long bones (humerus, femur, or tibia) have been subjected to a high amount of kinetic energy, which should dramatically increase your index of suspicion for serious occult (unseen) injuries. When a decision for rapid transport is made, use your backboard as a splinting device to splint the patient's whole body rather than individually splinting each extremity. If you take the extra time required to individually splint each of the patient's arms and legs, you may delay the prompt surgical intervention needed for other injuries when a significant MOI has occurred. Individual splints should be applied en route if the patient is stable (ie, the ABCs are stable) and time permits.

Patients with a simple MOI, such as a twisted ankle or dislocated shoulder, may be further assessed

on scene. Stabilize their conditions prior to transport if no other problems exist. Handle fractures carefully while preparing the patient for transport. Gentle care is necessary to limit pain and to prevent sharp bone ends from breaking through the skin or damaging nerves and blood vessels in the extremity.

History Taking

After the life threats have been managed during the primary survey, investigate the chief complaint. Obtain a medical history and be alert for injury-specific signs and symptoms and for any pertinent negatives such as no pain or loss of sensation.

Obtain information from the patient and any bystanders who witnessed it about what led to the incident. Specifically, determine the condition of the patient immediately before the incident, the details of the incident, and the patient's position after the incident. Ask the patient for a subjective description of the injury: How did this happen? Did you hear a pop? Do you have pain? Which functional limitations do you now have? Have you had any abnormal movement or loss of movement?

Remember to obtain a SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history for all trauma patients. How much you explore this history depends on the seriousness of the patient's condition and how quickly you need to transport the patient to the hospital.

For patients with simple fractures, dislocations, or sprains, it is easier to obtain a SAMPLE history. At the scene, you may have access to family members and others who have information about the patient's history. Try to obtain this history without delaying the time to definitive care. If time allows, complete the SAMPLE history to identify any pre-existing musculoskeletal disorders and attempt to learn more about the injury. Some information obtained will be very relevant to the injury (eg, the patient is taking anticoagulant medications or has a history of osteoporosis).

The OPQRST-I mnemonic (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, Interventions) is of limited use in cases of severe injury and is usually too time consuming to use when the patient's airway, breathing, circulation, and rapid transport require immediate attention.

However, OPQRST-I may be more useful when the MOI is unclear, the patient's condition is stable, details of the injury are uncertain, or evaluation of the patient's pain is necessary. In a case of simple trauma, this more detailed investigation may help you and the hospital staff to better understand the specific injury.

Words of Wisdom

When assessing a patient's pain, use the OPQRST-I mnemonic: Onset of the pain; Provoking or Palliating factors; Quality of the pain (eg, sharp, pressure, crampy); Region of the pain, including its primary location and the area where pain radiates or refers; Severity of the pain; Time (duration) that the patient has been experiencing pain; and any Interventions performed before EMS arrival on scene.

As mentioned, a person may experience acute pain in conjunction with a musculoskeletal injury. It is useful to have the patient quantify the severity of the pain by using a 1 to 10 pain scale or a pain scale that uses images of facial expressions to assess pain. Pain scales are presented in Chapter 36, *Pediatric Emergencies*.

Special Populations

Children with fractures may not want you to see, touch, or splint the injured extremity. Always be honest with children about what you are doing and whether it will hurt. Explain that splinting is necessary and sometimes painful, but that there will be less pain once the splint is in place, the fracture is stabilized, and cold packs are applied.

Secondary Assessment

The secondary assessment is a more detailed, comprehensive examination of the patient that can reveal injuries that may have been missed during the primary survey. In some cases, such as with a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment. If two or more extremities are injured, treat the patient as having experienced significant trauma and provide rapid transport to the hospital.

The likelihood of other, more severe injuries increases when two or more bones have been broken.

If the patient has suffered significant trauma that has likely affected multiple systems, start the secondary assessment with a full-body exam to confirm you have found all problems and injuries. Begin with the head and systematically work toward the feet. Assess the patient's head, chest, abdomen, genitalia, extremities, and back. This full-body exam will help you identify any hidden and potentially life-threatening injuries and will also help you prepare the patient for rapid transport. For example, you want to identify an unstable pelvis before you attempt to move the patient onto a backboard and secure the patient to the board.

When examining a stable patient with an isolated injury, obtain a baseline set of vital signs. Your focus can then shift to evaluating the injured extremity. One of the simplest ways to assess an extremity is to compare one side with the other, noting any discrepancy in length, position, or skin color.

Complete the secondary assessment by noting DCAP-BTLS (Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, Swelling) as you observe and palpate the soft tissue from head to toe and assess the patient for limitations, such as inability to move a joint. While performing the exam, ensure you cover the **six Ps of musculoskeletal assessment**: Pain, Paralysis, **Paresthesias** (numbness or tingling), Pulselessness, Pallor (pale skin or delayed capillary refill in children), and Pressure. Evaluate the circulation, motor function, and abnormal sensations distal to the injury.

During the secondary assessment, ensure you consider distracting injuries—that is, the injuries that are immediately obvious. In the case of an obvious open fracture of the femur, a patient might direct you only to the site of greatest pain. Distal extremity injuries (fractures and dislocations of the feet and hands) are commonly overlooked due to a distracting injury.⁶

Assess the entire zone of injury. Remove clothing from the area and look and palpate for injuries. In musculoskeletal injuries, this zone generally extends from the joint above (proximal) to the joint below (distal), front and back. Always evaluate the joint above and below the site of injury because the injuring force may have affected these sites as well.

Inspection

Inspect for the following signs:

- Deformity, including asymmetry, angulation, shortening, and rotation
- Skin changes, including contusions, abrasions, avulsions, punctures, burns, lacerations, and bone ends
- Swelling
- Muscle spasms
- Abnormal limb positioning
- Increased or decreased range of motion
- Color changes, including pallor and cyanosis
- Bleeding, including estimating the amount of blood loss

Palpation

Palpate for tenderness, which, like contusions or abrasions, may be the only significant sign of an underlying musculoskeletal injury. In addition to palpating the injury site, palpate the regions above and below it, identifying any regions with point tenderness (those that the patient identifies as painful). Frequently reassess any tender areas to determine whether the location or severity of the pain or tenderness has changed. Although point tenderness is one of the best indicators of an injury, it may be absent in patients who are intoxicated or who have an injury to the spinal cord.

When you palpate an injured site, attempt to identify instability, deformity, abnormal joint or bone continuity, and displaced bones. Feel for crepitus, which is commonly found at the site of a fracture. Palpate distal pulses on all extremities, and pay special attention to comparing the strength of the pulses in the injured extremity with those in a normal one.

Occasionally, evidence of an arterial injury may be identified while palpating an extremity. Signs of an arterial injury include a pulsatile expanding hematoma, diminished or absent distal pulses, a palpable thrill (vibration) over the site of injury that correlates with the patient's heartbeat, and bleeding that is difficult to control.

Palpate the pelvis to identify instability and point tenderness. Apply pressure over the pubic symphysis to evaluate for tenderness and crepitus. Next, press the iliac wings toward the midline and then posteriorly. Any gross instability found during

this examination should be reported to hospital personnel; it may indicate a severe pelvic injury. Do not repeatedly examine the pelvis if instability is found because the manipulations may disrupt blood clots and cause further bleeding.

The examination of the upper and lower extremities should include independently palpating the entire length of each arm and leg to identify any sites of injury. The most efficient way to accomplish this is to place your hands around the extremity and squeeze. Repeat this procedure every few centimeters until you reach the end of the extremity. When you evaluate the upper extremities, always examine the cervical spine and shoulder, because complaints within the arm may be caused by a more proximal disorder. Likewise, with the lower extremities, always conduct an examination of the pelvis and hip if the patient complains of pain in the leg.

If your assessment reveals no external signs of injury, ask the patient to carefully move each limb, and to stop immediately if a movement causes pain. Skip this step in your evaluation if the patient reports neck or back pain. Even slight movement can cause permanent damage to the spinal cord.

Neurovascular Status

Many important blood vessels and nerves lie close to bones, especially around the major joints. Therefore, any injury or deformity of a bone may be associated with vessel or nerve injury. For this reason, you must assess neurovascular function every 5 to 10 minutes during the care process, depending on the patient's condition, until the patient is at the hospital. Always recheck the patient's neurovascular function before and after you splint or otherwise manipulate the limb, as manipulation may potentially cause a bone fragment to press against or impale a nerve or vessel. Failure to restore circulation in this situation can lead to death of the limb. Always give priority to patients with impaired circulation resulting from bone fragments. To assess neurovascular status, follow the steps in **SKILL DRILL 33-1**.

Because many of the steps in the detailed physical exam require patient cooperation, you will not be able to assess sensory and motor function in an unresponsive patient. Nevertheless, you can evaluate an unresponsive patient's limb for deformity, swelling, ecchymosis, false motion, and crepitus.

Skill Drill 33-1 Assessing Neurovascular Status**Step 1**

Palpate the radial pulse in the upper extremity.

**Step 2**

Palpate the posterior tibial and dorsalis pedis pulses in the lower extremity.

**Step 3**

Assess capillary refill by blanching a fingernail or toenail. If normal color does not return within 2 seconds after you release the nail, then assume circulation is impaired. This test is typically recommended for children, although it can be used in adults as well.

**Step 4**

Assess sensation in the flesh near the tip of the index finger and thumb, as well as the little finger. The patient's ability to sense a light touch in the fingers or toes distal to the site of a fracture is a good indication that the nerve supply is intact.

**Step 5**

On the foot, check sensation on the flesh near the tip of the big toe.

**Step 6**

Check sensation on the medial side of the foot.

Skill Drill 33-1 Assessing Neurovascular Status (*continued*)**Step 7**

For an upper extremity injury, evaluate motor function by asking the patient to open the hand. (Perform motor tests only if the hand or foot is not injured. Stop the test if it causes pain.)

**Step 8**

Ask the patient to make a fist.

**Step 9**

For a lower extremity injury, ask the patient to flex the foot and toes downward.

© Jones & Bartlett Learning.

**Step 10**

Ask the patient to extend the foot and ankle and pull the toes and foot upward.

Words of Wisdom

Extremity injuries that impair circulation or nerve function in distal tissues are urgent situations. Patients with these injuries need careful assessment, prompt transport, and frequent reassessment of distal functions. It is also crucial to report this information in your initial radio contact with the hospital to allow personnel to prepare for prompt diagnostic evaluation and potentially surgery, which may be necessary to save the limb.

Vital Signs

Determine a baseline set of vital signs, including pulse rate, rhythm, and quality; respiratory rate, rhythm, and quality; blood pressure; skin condition; and pupil size and reaction to light. Obtain these baseline indicators as soon as possible. The patient may appear to be tolerating the injury well—at least, until you reassess these vital signs and they indicate otherwise. Trends in vital signs can indicate whether the patient's condition is improving

or getting worse over time, particularly during long transports. Shock or hypoperfusion is common in musculoskeletal injuries, and the baseline information provided by the vital signs is very important in assessing for these conditions. In addition, remember to assess blood glucose levels in all patients who present with altered mental status.

Assessment Pearls

- Remove jewelry or other items from injured extremities to prevent constriction from swelling.
- Pain out of proportion to the apparent injury is the hallmark for compartment syndrome.
- Never place an amputated part directly on ice! Doing so can result in frostbite.
- Use extreme care with geriatric patients when applying a traction splint. Aggressive placement could result in another fracture in people with osteoporosis.
- For a pulseless extremity, make one attempt to place the extremity in a neutral position to restore a pulse. Regardless of whether the pulse is restored, splint in the new position and document results.

Reassessment

Repeat the primary survey to ensure your interventions are working as they should. A reassessment should be performed every 5 minutes for a patient in unstable condition and every 15 minutes for a patient in stable condition.

Because trauma patients often have multiple injuries, ensure you assess their overall condition, stabilize the ABCs, and control any serious bleeding before further treating the injured area. Consider calling early for paramedic backup if needed. In a critically injured patient, you should secure the patient to a long backboard to stabilize the spine, pelvis, and extremities and provide prompt transport to a trauma center. In this situation, a secondary assessment with extensive evaluation and splinting of

limb injuries in the field is a waste of valuable time. Instead, perform the primary survey at the scene and provide rapid transport, reassessing the patient en route to the ED.

If the patient has no life-threatening injuries, you may take extra time at the scene to stabilize any obvious injuries and perform a more thorough evaluation.

Words of Wisdom

Always splint a joint above and a joint below the injury, and assess the patient's circulation, motor function, and sensation both prior to and after splinting. Stabilize the injury in the most comfortable position that allows for maintenance of good circulation distal to the injury.

Your radio report to the hospital should include a description of the problems found during your assessment. Report problems with the patient's ABCs, open fractures, and compromised circulation that occurred before or after splinting and that may require specialized care.

In your documentation, give complete descriptions of injuries and the MOIs associated with them. It is important to assess and document the presence or absence of circulation, motor function, and sensation distal to the injury before you move an extremity, after manipulation or splinting of the injury, and on arrival at the hospital. In other words, always document the findings of a neurovascular exam, even if they are normal. When an abnormality is identified, document the specific deficit; for example, the patient was unable to extend the thumb or move the wrist. Hospital staff may later refer to your notes to compare changes to the patient's condition over time. In addition, your careful documentation may protect you from legal action if patients or their families pursue it later. Do not rely on your memory to recall details from situations; your memory is unreliable and will not hold up in a court of law.

Words of Wisdom

Musculoskeletal injuries are rarely an immediate threat to life. Remember the ABCs!

Emergency Medical Care

Your first steps in providing care for any patient are the primary survey and stabilizing the patient's ABCs. If needed, perform a rapid full-body scan or focus on a specific injury. Remember to always

take standard precautions and be alert for signs and symptoms of internal bleeding. Internal bleeding should be suspected whenever the MOI suggests that severe forces have affected the body. Consider administering nitrous oxide for pain relief as indicated by local protocols.

Follow the steps in **SKILL DRILL 33-2** when caring for patients with musculoskeletal injuries.

Words of Wisdom

Straightening or splinting an injured limb can compromise distal functions, just as the initial injury can. Record the status of distal circulation and nervous function (neurovascular status) before and after splinting. At a minimum, your written record should describe these functions before splinting, immediately after splinting, and on arrival at the hospital. Also indicate the results of reassessments en route.

Volume Deficit Due to Musculoskeletal Injuries

Fractures may lead to significant blood loss from damaged blood vessels within the bone and

musculature around the bone and, in some cases, from damage to large blood vessels in the region of the fracture. When you care for patients with fractures, implement interventions such as applying direct pressure, splinting, and administering IV fluids to prevent the development of hypotension and an unstable condition. **TABLE 33-3** lists the potential amounts of blood loss from various fracture sites and may serve as a guideline for estimating the level of resuscitation required.

Words of Wisdom

Remember: XABCDE! Control any exsanguinating hemorrhage, then quickly proceed to the ABCs. Avoid tunnel vision and focus on the entire patient, including rapid stabilization and transport to definitive care.

For patients who are at risk for hypovolemia from fractures, such as pelvic fractures or bilateral femur fractures, IV access should be gained and an isotonic crystalloid solution given. To ensure adequate perfusion, administer fluids in 20-mL/kg increments to maintain blood pressure at 80 to 90 mm Hg systolic.

YOU are the Provider

Part 3

After you have the patient situated in the back of the ambulance, you ask your partner to initiate rapid transport to the trauma center, which is approximately 45 minutes away, attempting to keep the ride as smooth as possible to minimize the patient's pain and discomfort. As you obtain the patient's baseline vital signs, you decide the patient would benefit from having a second IV line inserted because of the potential for significant blood loss. You establish a second 18-gauge IV line with normal saline TKO (to keep open). Although the patient is in a moderate amount of pain, he states the pain is bearable.

Recording Time: 14 Minutes

Respirations	24 breaths/min, clear
Pulse	122 beats/min
Skin	Cool, pale, and clammy
Blood pressure	92/40 mm Hg
Oxygen saturation (SpO₂)	97% on 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- What are some potential complications of femur and pelvic fractures?
- What are the considerations when using lactated Ringer solution with trauma patients?

Skill Drill 33-2 Caring for Musculoskeletal Injuries

Step 1

Cover open wounds with a dry, sterile dressing, and apply direct pressure to control bleeding. Assess distal pulse and motor and sensory function. If bleeding cannot be controlled, then apply a tourniquet.

Step 2

Apply a splint, and elevate the extremity approximately 6 inches (15 cm) (slightly above the level of the heart). Assess distal pulse and motor and sensory function.

Step 3

Apply cold packs if there is swelling, but do not place them directly on the skin.

Step 4

Position the patient for transport, and secure the injured area. Consider requesting paramedic backup for additional pain management.

TABLE 33-3 Potential Blood Loss From Fracture Sites

Fracture Site	Potential Blood Loss (mL)
Pelvis	1,500–3,000
Femur	1,000–1,500
Humerus	250–500
Tibia or fibula	250–500
Ankle	250–500
Elbow	250–500
Radius or ulna	150–250

© Jones & Bartlett Learning.

Cold and Heat Application

Cold packs are useful for treating patients during the initial 48 hours following an injury and are very effective at decreasing both pain and swelling. Cooling the injured area causes vasoconstriction of the blood vessels in the region and decreases the release of inflammatory mediators. As a result, swelling and inflammation are reduced when cold packs are used during the acute stage of an injury.

Conversely, heat therapy should generally be avoided during the initial 48 to 72 hours following an injury, because heat may increase pain and swelling during this period. Once the acute phase of the injury ends and clotting occurs in damaged blood vessels, heat packs are useful for increasing

blood flow to the region to decrease stiffness and to promote healing. Consequently, heat packs may be beneficial for patients who report an injury that occurred several days before contacting EMS.

Splinting

A **splint** is a flexible or rigid device that is used to protect and maintain the position of an injured extremity (**FIGURE 33-24**). Unless the patient's life is in immediate danger, you should splint all fractures, dislocations, and sprains before moving the patient. Splinting an injured extremity properly not only decreases the patient's pain, but splinting also reduces the risk of further damage to muscles, nerves, blood vessels, and skin. In addition, splinting helps to control bleeding by allowing clots to form where vessels were damaged.

A splint is simply a device to prevent motion of the injured part. It can be made from any material when you need to improvise. However, you should have an adequate supply of standard commercial splints on hand. When no splinting materials are available, the patient's arm can be bound to the chest wall, and an injured leg can be bound to the uninjured leg to provide at least temporary stability. The three major types of splints are traction splints, rigid splints, and formable splints.

When a patient with multiple orthopaedic injuries must be transported immediately, you will not have time to splint each fracture one by one. Instead, the best way to stabilize multiple fractures when the patient's overall condition is critical is

to splint the axial skeleton by using a long back-board and straps or an alternative device, such as a vacuum mattress. This will serve three purposes: (1) protect against a spinal injury; (2) reduce movement of the injured extremities by securing them to the board; and (3) save time at the scene.

Words of Wisdom

One of the primary indications for splinting is to prevent a closed fracture from becoming an open fracture (conversion).

Principles of Splinting

The following principles of splinting apply to most situations:

1. Remove clothing from the area of any suspected fracture or dislocation so you can inspect the extremity for DCAP-BTLS. Also, remove any jewelry, as swelling may cause rings or watches to cut off circulation.
2. Assess and record the patient's neurovascular status distal to the site of the injury, including pulse, sensation, and movement. Reassess frequently en route to the hospital.
3. Cover all wounds with a dry, sterile dressing before splinting. To prevent infection following an open fracture, brush away any obvious debris on the skin surrounding an open fracture before applying the dressing. Do not enter or probe the open fracture site to retrieve debris, because this may lead to further contamination. Do not attempt to push exposed bone ends back under the skin.
4. Do not move the patient before splinting an extremity unless there is an immediate hazard to the patient or yourself.
5. For *fractures*, the splint should immobilize the bone ends and the two adjacent joints—above and below the fracture. For *dislocations*, the splint must extend along the entire length of the bone above and the entire length of the bone below the dislocated joint.
6. Pad all rigid splints to prevent local pressure and discomfort to the patient.
7. Manually support the injured site with hands placed above and below the injury to minimize movement until the splint is applied and secured.

FIGURE 33-24 Splinting reduces pain and prevents additional damage to an injured extremity. Maintain manual support of the injured extremity during bandaging and splinting.

© Courtesy of Rhonda Hunt.

8. If a long bone fracture is severely angulated and no pulse is present in the extremity, gently apply longitudinal traction (tension) to attempt to realign the bone and improve circulation. Use a smooth, firm grip to apply manual traction, and avoid any sudden, jerky movements of the limb. *Do not attempt to straighten fractures involving joints without first obtaining medical direction.* There is no need to straighten or manipulate the joint unless it has no distal pulse.
9. If the patient reports severe pain or is resistant to movement, discontinue applying traction, splint the joint or bone in the position of deformity, and carefully monitor the distal neurovascular status.
10. If possible, avoid covering the fingers and toes with the splint to allow for monitoring of skin color, temperature, and condition.
11. If possible, apply cold packs and elevate the splinted limb to minimize swelling.
12. Stabilize all suspected spinal injuries in a neutral, in-line position on a long backboard.
13. If the patient has signs of shock (hypoperfusion), align the limb in the normal anatomic position and provide transport.
14. When in doubt, splint.

Be aware of the hazards associated with the improper application of splints, which include the following:

- Compression of nerves, tissues, and blood vessels
- Delay in transport of a patient with a life-threatening injury
- Reduction of distal circulation
- Aggravation of the injury
- Injury to tissue, nerves, blood vessels, or muscles due to excessive movement of the bone or joint

Words of Wisdom

When treating a patient with multiple serious fractures, immediately secure the patient to a long backboard and provide rapid transport. Spending time on scene immobilizing individual non-life-threatening injuries may result in a well-splinted corpse!

Traction Splints

Applying in-line **traction** is the act of exerting a pulling force on a body structure in the direction of its normal alignment. It is the most effective way to realign a fracture of the shaft of a long bone so the limb can be splinted more effectively. Following a femur fracture, the strong muscles of the thigh go into spasm, a condition that often leads to significant pain and deformity. Traction splints provide constant pull on a fractured femur, thereby preventing the broken bone ends from overriding due to unopposed muscle contraction. In addition, these splints help maintain alignment of the fracture pieces and provide effective stabilization of the fracture site. As a result, patients are likely to experience less pain.

Traction splints also reduce blood loss. Normally, the thigh is shaped like a cylinder. In a femur fracture, the thigh is shortened and becomes spherical. The volume of a sphere can be substantially greater than that of a cylinder, so a person with an untreated femur fracture can accumulate more blood in the thigh than a person whose thigh is pulled out to length by a traction splint.

Excessive traction can be harmful to an injured limb. When applied correctly, however, traction stabilizes the bone fragments and improves the overall alignment of the limb. Do not attempt to reduce the fracture or force all the bone fragments back into alignment. This is the physician's responsibility and is outside the AEMT's scope of practice. In the field, the goals of in-line traction are as follows:

- To stabilize the fracture fragments to prevent excessive movement
- To align the limb sufficiently to allow it to be placed in a splint
- To avoid potential neurovascular compromise

The amount of pull that is required to accomplish these objectives varies, but rarely exceeds 15 pounds (7 kg). Use the least amount of force necessary. Firmly grasp the patient's foot at the end of the injured limb; once you start pulling, do not stop until the limb is fully splinted. When pulling traction for a possible femur fracture, place one hand underneath the patient's knee for support. The direction of traction pull is always along the long axis of the limb. Imagine where the normal, uninjured limb would lie, and pull gently along the line of that imaginary limb until the injured limb is in

FIGURE 33-25 To apply traction, imagine the position where the normal uninjured limb would lie, then gently pull along that line until the injured limb is in that position. Do not release traction once you have applied it.

© Jones & Bartlett Learning.

approximately that position (**FIGURE 33-25**). Grasping the foot and the initial pull of traction usually causes some discomfort as the bone fragments move. It helps if a second person can support the injured limb directly under the site of the fracture. This initial discomfort will quickly subside, and you can then apply further, gentle traction. However, if the patient strongly resists the traction or if it causes more pain that persists, then stop and splint the limb in the deformed position.

Traction splints are used primarily to stabilize isolated fractures of the midshaft femur, which are characterized by pain, swelling, and deformity of the midthigh. Do not use a traction splint if the patient has a joint or lower leg injury. Several different types of lower extremity traction splints are commercially available, such as the Hare traction splint, the Sager traction splint, the Reel splint, and the Kendrick splint. Become familiar with the unique method of applying each one. (The uses of the Hare and Sager splints are described later in this section.) Consult with your local agency on

which traction splint you will use in the field, and ensure you are comfortable applying this device to a patient.

Traction splints are not suitable for use on the upper extremities because the major nerves and blood vessels in the patient's axilla cannot tolerate countertraction forces. In addition, do not use traction splints in patients with any of the following conditions:

- Injuries close to or involving the knee
- Injuries of the pelvis
- Partial amputations or avulsions with bone separation
- Lower leg, foot, or ankle injury

Proper application of a traction splint requires two well-trained providers working together. To apply a Hare traction splint, follow the steps in **SKILL DRILL 33-3**. Because the Hare traction splint stabilizes the limb by producing countertraction on the ischium and in the groin, you should pad these areas well. Avoid excessive pressure on the external

Words of Wisdom

When you apply traction to an injured lower extremity, place one hand underneath the patient's knee to provide support for the joint and grasp under the patient's ankle with your other hand to pull traction.

Words of Wisdom

A traction splint is used *only* for an isolated femur fracture. Do not spend valuable time on scene applying a traction splint on a critical patient; if time permits, it can be applied en route once other life threats have been addressed.

Skill Drill 33-3 Applying a Hare Traction Splint**Step 1**

Take standard precautions. Expose the injured limb and check the pulse and motor and sensory function. Place the splint beside the uninjured limb, adjust the splint to the proper length, and prepare the straps.

**Step 2**

Support the injured limb as your partner fastens the ankle hitch about the foot and ankle. Usually, the patient's shoe is removed for this procedure.

**Step 3**

Continue to support the limb as your partner applies gentle in-line traction to the ankle hitch and foot.

**Step 4**

Slide the splint into position under the injured limb until it seats against the ischial tuberosity, while your partner supports the heel and underneath the calf.

Skill Drill 33-3 Applying a Hare Traction Splint (continued)

Step 5

Pad the groin and fasten the ischial strap.

Step 6

Connect the loops of the ankle hitch to the end of the splint as your partner continues to maintain traction. Carefully tighten the ratchet to the point the splint holds adequate traction. Adequate traction has been applied when the leg is the same length as the uninjured leg or when the patient's pain is relieved.

Step 7

Secure and check the support straps; take care not to place a strap over the fracture site. Reassess the patient's pulse and motor and sensory function.

Step 8

Secure the patient and splint to the backboard in a way that will prevent movement of the splint during patient movement and transport.

genitalia. Always use commercially available padded ankle hitches rather than pieces of rope, cord, or tape; such improvised hitches can sometimes be painful and can potentially obstruct circulation in the foot.

The Sager traction splint is lightweight, easy to store, and applies a measurable amount of traction. Best of all, you can apply it by yourself when necessary. To apply a Sager traction splint, follow the steps in **SKILL DRILL 33-4**.

Skill Drill 33-4 Applying a Sager Traction Splint

Step 1

Take standard precautions and expose the injured area. Check the patient's pulse and motor and sensory functions. Adjust the thigh strap so it lies anteriorly when secured.

Step 2

Estimate the proper length of the splint by placing it next to the uninjured limb. Fit the ankle pads to the ankle.

Step 3

Place the splint at the inner thigh, apply the thigh strap at the upper thigh so the perineal cushion is snug against the groin and the ischial tuberosity, and secure the splint snugly.

Step 4

Tighten the ankle harness just above the malleoli. Pull and secure the cable ring against the bottom of the foot.

Step 5

Extend the splint's inner shaft to apply traction of approximately 10% of the patient's body weight, using a maximum of 15 pounds (7 kg).

Step 6

Secure the splint with elasticized cravat bandages.

Skill Drill 33-4 Applying a Sager Traction Splint (*continued*)

Step 7

Secure the patient to a long backboard. Reassess pulse and motor and sensory function.

Words of Wisdom

The Reel splint, used primarily by the military, is designed to be used on a lower extremity (**FIGURE 33-26**). It provides the option to stabilize the joint or bone in the position found and, with the hinges, can be adjusted without removing the splint.

FIGURE 33-26 The Reel splint is being used by the military.

Courtesy of Reel Research & Development, Inc. [www.splints.com].

Rigid Splints

Rigid (nonformable) splints are made from firm material and are applied to the sides, front, and/or back of an injured extremity to prevent motion at the injury site. Common examples of rigid splints include padded board splints, molded plastic and metal splints, padded wire ladder splints, and folded cardboard splints. As always, take standard precautions. It takes two AEMTs to apply a rigid splint. Follow the steps in **SKILL DRILL 33-5**.

There are two situations in which you must splint the limb in the position of deformity: (1) when the deformity is severe, as is the case with many dislocations, and (2) when you encounter resistance or extreme pain when applying gentle traction to the fracture of a shaft of a long bone. You should only attempt to straighten an extremity if there is no pulse. If a pulse is present, it should not be manipulated, just splinted in the position found. In either situation, you should apply padded board splints to each side of the limb and secure them with soft roller bandages (**FIGURE 33-27**). Most dislocations should be splinted as found, but follow local protocols. Attempts to realign or reduce dislocations can lead to more damage.

Pneumatic Splints

Pneumatic splints are useful for stabilizing fractures involving the lower leg or forearm. They are not effective for angulated fractures or for fractures that involve a joint, because they will forcefully attempt to straighten the fracture or joint.

Air Splints

The most commonly used pneumatic splint is the precontoured, inflatable, clear-plastic air splint. These devices are available in a variety of sizes and shapes, with or without a zipper that runs the length of the splint. Always inflate this kind of splint *after* applying it.

The air splint is comfortable, provides uniform contact, and has the added advantage of applying firm pressure to help control bleeding and reduce

Skill Drill 33-5 Applying a Rigid Splint

Step 1

Provide gentle support and in-line traction for the limb. Assess distal pulse and motor and sensory function.

Step 2

Place the splint alongside or under the limb. Pad between the limb and the splint as needed to ensure even pressure and contact. Pad any bony prominences.

Step 3

Secure the splint to the limb with bindings.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 4

Assess and record distal neurovascular function.

FIGURE 33-27 If you encounter resistance or extreme pain when applying traction to a long bone, apply padded board splints to each side of the limb, and secure them with soft roller bandages, stabilizing the limb in its deformed position.

© American Academy of Orthopaedic Surgeons.

swelling. These splints should not be used on open fractures in which any sharp bone ends are exposed. All open wounds must be covered with a dressing before applying these splints.

Air splints have some drawbacks, particularly in areas prone to cold weather. The zipper can stick, clog with dirt, or freeze. Significant changes in the weather affect the pressure of the air in the splint. Therefore, carefully monitor air splints to ensure they do not lose pressure or become overinflated. Overinflation can occur when the splint is applied in a cold area and the patient is subsequently moved to a warmer area—the air inside the splint will

expand as it gets warmer, possibly increasing pressure and causing pulses to cease. The same thing happens when there are changes in altitude, which can be a problem with air transport of patients. Air splints will expand in a higher altitude if the patient compartment of the aircraft is unpressurized (eg, in a helicopter). Therefore, carefully monitor the splint and let out air if the splint becomes overinflated.

The method of applying an air splint depends on whether it has a zipper. With either type (zippered or unzippered), you must first cover all wounds with a dry, sterile dressing, ensuring you take standard precautions. Using a pump or, if local protocols allow, oxygen tubing and your oxygen tank, inflate the splint just to the point at which finger pressure will make a slight dent in the splint's surface.

Pneumatic Antishock Garments

If a patient has injuries to the lower extremities or pelvis, you may be able to use a pneumatic antishock garment (PASG) as a splinting device, if local protocol allows. Situations in which use of a PASG is allowed vary widely by locale. Many EMS systems no longer use this device because of problems reported with its use. The PASG is contraindicated for treatment of shock but may have some value as a splinting device in rare circumstances.

Words of Wisdom

The primary use of the PASG is to stabilize pelvic fractures or bilateral femur fractures. This device may also be beneficial for applying pressure to help control bleeding in the lower extremities when injuries cover a large surface area.

Do not use the PASG if any of the following conditions exist, as the PASG may worsen or complicate the patient's condition:

- Pregnancy
- Pulmonary edema
- Acute heart failure
- Penetrating chest injuries
- Groin injuries
- Major head injuries

Consult with medical direction if you think prolonged use or use in unusual circumstances may be necessary.

If you are using the device to stabilize a possible pelvic fracture, you must inflate all compartments.

Do not remove a PASG in the field. This type of splint must be deflated gradually in the hospital under careful supervision by a physician. Before handing off the patient to hospital personnel, report the patient's blood pressure, the time you applied the PASG, and the results.

Formable Splints

Formable splints include vacuum splints, pillow splints, structural aluminum malleable (SAM) splints, a sling and swathe, and pelvic binders for pelvic fractures.

Vacuum Splints

Just like an air splint, a vacuum splint can be easily shaped to fit around a deformed limb. Instead of pumping in air, however, you use a hand pump to pull out the air through a valve. Follow the steps in **SKILL DRILL 33-6** to apply a vacuum splint.

Special Populations

Because vacuum mattresses conform to the body, they may be the best choice to immobilize older adult patients who have abnormal curvatures of the spine and are suspected of having spinal column injuries.

Pelvic Binder

Pelvic binders are used to splint the bony pelvis to reduce hemorrhage from bone ends, venous disruption, and pain (**FIGURE 33-28**). Pelvic binders are meant to provide temporary stabilization until definitive stabilization can be achieved. Generally, pelvic binders should be light, made of soft material, and easily applied by one person, and they should allow access to the abdomen, perineum, anus, and groin for examination and diagnostic testing. Because there are various manufacturers of pelvic binder devices, you should be familiar with the manufacturer's instructions for your specific device.

Buddy Splinting

Buddy splinting is used to splint injuries that involve the fingers or toes. With this technique, an adjacent uninjured finger or toe serves as a splint to the injured one. To buddy splint, tape the injured digit to

Skill Drill 33-6 Applying a Vacuum Splint

Step 1

Assess distal pulse and motor and sensory functions. Have your partner stabilize and support the injury, applying traction if needed.

Step 2

Place the splint and wrap it around the injured limb.

Step 3

Draw out the air from the splint through the suction valve, and then seal the valve. Reassess distal pulse and motor and sensory function.

FIGURE 33-28 Pelvic binders are meant to provide temporary stabilization until definitive stabilization can be achieved.

© Jones & Bartlett Learning.

an uninjured one. Place a gauze pad between the digits that are taped together, and ensure the tape does not pass over joints. Ensure the tape is not so tight as to cut off circulation.

Transportation

Once an injured limb is adequately splinted, the patient is ready to be transferred to a backboard or stretcher and transported.

Very few, if any, injuries justify the use of excessive speed during transport. The limb will be stable once a dressing and splint have been applied. Although a patient with a pulseless limb or possible compartment syndrome must be given a high

priority, if the hospital is only a few minutes away, speeding to the ED will make no difference to the patient's eventual outcome. If the treatment facility is more than an hour away, the patient with a pulseless limb should be transported by helicopter or immediate ground transportation. If circulation in the distal limb is impaired, always consult medical direction so the proper steps can be taken quickly once the patient arrives in the ED.

Pathophysiology, Assessment, and Management of Complications of Musculoskeletal Injuries

Musculoskeletal injuries can lead to numerous complications—not just those involving the musculoskeletal system, but also systemic changes or illness. It is essential to not focus all your attention on the musculoskeletal injury; such “tunnel vision” may cause you to miss less obvious but more serious injuries.

The likelihood of developing a complication is often related to the strength of the force that caused the injury, the injury's location, and the patient's overall health. Any injury to a bone, muscle, or other musculoskeletal structure is often accompanied by bleeding. In general, the greater the force that caused the injury, the greater the hemorrhage that will be associated with it.

Following a fracture, the sharp ends of the broken bone may damage muscles, blood vessels,

arteries, and nerves, or the ends may penetrate the skin and produce an open fracture. A significant loss of tissue may occur at the fracture site if the muscle is severely damaged or if the bone's penetration of the skin causes a large defect. To prevent infection following an open fracture, you should brush away any obvious debris on the skin surrounding an open fracture before applying a dressing. Do not enter or probe the open fracture site to retrieve debris, because this may lead to further contamination.

Long-term disability is one of the most devastating consequences of a musculoskeletal injury. In many cases, a severely injured limb can be repaired and made to look almost normal. Unfortunately, many patients cannot return to work for long periods of time because of the extensive rehabilitation required and because of chronic pain. AEMTs have a critical role in mitigating the risk of long-term disability. By preventing further injury, reducing the risk of wound infection, minimizing pain through the application of cold and administration of analgesia, and transporting patients with musculoskeletal injuries to an appropriate medical facility, you help reduce the risk or duration of long-term disability.

Peripheral Nerve and Vascular Injuries

When blood vessels are damaged following a musculoskeletal injury, the patient may experience **devascularization**—that is, the loss of blood to a part of the body. Vessel injuries may include a contusion of the vessel wall, laceration, kinking or bending, and formation of pseudoaneurysms. Additionally, neurovascular injuries can occur. The skeletal system normally protects the neurovascular structures within the limbs from injury. These critical structures typically lie deep within the limb and close to the skeleton. For example, the brachial plexus is situated within the axilla and the inner aspect of the arm, shielded from injury by the shoulder girdle. When the shoulder girdle or proximal humerus is fractured, displaced fracture fragments may lacerate or impale nerves, leading to a neurologic deficit. Neurovascular injuries are also likely to occur following a joint dislocation because the nerves and vessels in the region of a joint tend to be more securely tethered to the soft tissues and are less likely to escape injury.

Special Populations

Pregnancy creates the potential for additional complications with musculoskeletal injuries, especially with a pelvic fracture. Any force significant enough to fracture the pelvis may injure the fetus or the interface between the placenta and the uterus. Aside from direct force, injuries may occur from broken bone ends penetrating the uterus. Significant bleeding may result in fetal death caused by the shunting of blood as her body attempts to protect the mother. Aggressive care of the pregnant woman, especially one with signs of shock, provides the best chance for a positive outcome for both patients.

Regardless of the type of vascular injury involved, it is important to assess and reassess pulses, control bleeding, and maintain adequate intravascular volume by administering IV fluid.

Compartment Syndrome

Within a limb, groups of muscles are surrounded by an inelastic membrane called **fascia** that confines the muscles to an enclosed space, or compartment. This compartment can accommodate only a limited amount of swelling. When bleeding or swelling occurs within a compartment as the result of a fracture or severe soft-tissue injury, the pressure within the compartment rises. Pressure that is too high may impair circulation and lead to pain, sensory changes, and progressive muscle death. This condition, known as **compartment syndrome**, is one of the most devastating consequences of a musculoskeletal injury. The longer this situation persists, the greater the chance for tissue necrosis (death).

Both external and internal factors can lead to the development of compartment syndrome. External factors include a bandage, splint, cast, or PASG that is applied too tightly and restricts circulation. Internal factors can increase the amount of material within a compartment. For example, bleeding within a compartment may occur because of a fracture, dislocation, crush injury, vascular injury, soft-tissue injury, or bleeding disorder. Alternatively, fluid leakage or edema may occur secondary to ischemia with reperfusion, excessive exercise, trauma, burns, or any condition associated with the leakage of proteins and fluid from vessels into the interstitial space. A common misconception is that open fractures are safe from compartment syndrome—that is not true. Open fractures may actually have a higher risk of compartment syndrome because they are typically associated with higher-energy injuries and because the open injury

typically results in inadequate decompression of the compartment to alleviate the increased swelling that results.

Compartment syndrome usually develops within 6 to 12 hours after injury. It is characterized by severe pain that is localized to the involved compartment and often described as out of proportion to the injury due to the passive stretching of the muscles from the pressure increasing in the compartment. This pain is typically not relieved with pain medication, including narcotics.

As time progresses, the affected area may feel very firm, although this is an unreliable sign. Skin pallor may be apparent as well as paresthesias, such as a burning sensation, numbness, or tingling, and paralysis of the involved muscles. Another late sign of compartment syndrome is absence of distal pulses in the affected extremity. By the time the pressure within the compartment reaches the point where it totally occludes the artery passing through it, significant muscle necrosis has probably occurred.

Words of Wisdom

Provide rapid transport for a patient who shows evidence of compartment syndrome. There is no treatment for this syndrome other than surgery!

Words of Wisdom

The potential for compartment syndrome increases dramatically with the presence of circumferential burns. Damaged tissue that is unable to expand with the increased edema within the tissues results in increasing pressures and, ultimately, compartment syndrome.

If a patient has a fracture below the elbow or the knee, ask about the following: extreme pain, decreased pain sensation, pain on stretching of affected muscles, and decreased strength. These signs and symptoms may suggest the pressure within a fascial compartment is elevated; that is, compartment syndrome may be developing.

The goal of prehospital care is to deliver the patient with compartment syndrome to an emergency facility before the extremity is pulseless. Thus, management should include elevating the extremity to heart level (not above), placing ice packs over the extremity, and opening or loosening constrictive clothing and splint material. Administer oxygen and crystalloid solution as needed. Consider administering nitrous oxide for pain management as allowed by local protocols. Provide immediate transport, and frequently reassess the patient's neurovascular status during transport. Compartment syndrome must be managed surgically.

Crush Syndrome

Crush syndrome occurs when a prolonged compressive force impairs muscle metabolism and circulation following the extrication or release of an entrapped limb. When muscles are crushed beyond repair, tissue necrosis develops and leads to release of harmful products, a process known as **rhabdomyolysis**. Rhabdomyolysis may also lead to compartment syndrome. This condition may arise not only in trauma patients, but also in patients who have been lying on an extremity for an extended period (4 to 6 hours of compression); for example, when a patient who experienced a drug overdose or stroke is not found for an extended period (**FIGURE 33-29**).

After a muscle is compressed for 4 to 6 hours, the muscle cells begin to die and release their contents into the localized vasculature. When the force compressing the region is removed, blood flow is reestablished and the material from the cells that was released into the local vasculature quickly returns to the systemic vasculature. The substances that are of primary concern during this process are lactic acid, potassium, and myoglobin. This process is likely to result in decreased blood pH (acidemia), hyperkalemia, and renal dysfunction.

FIGURE 33-29 Crush injury with tissue necrosis. The patient laid on this hand for hours, resulting in injury.

© Courtesy of Rhonda Hunt.

Treatment of crush syndrome, which aims to prevent complications caused by toxin release, should always be performed with medical direction. Many steps must be taken *before* releasing the compressing force. As with all patients, assess the ABCs in case of suspected crush syndrome. Administer supplemental oxygen as needed, and then consider administering a bolus of crystalloid solution to increase the intravascular volume and to protect the kidneys from the forthcoming myoglobin load. Do not apply a compressive device such as a PASG. Medical control may advise applying a tourniquet prior to extrication when an extremity is involved.

Thromboembolic Disease

Thromboembolic disease, including **deep vein thrombosis (DVT)** and **pulmonary embolism**, is a significant cause of death during the days and weeks after musculoskeletal injuries, especially injuries to the pelvis and lower extremities that lead to prolonged immobilization. Signs and symptoms of DVT include disproportionate swelling of an extremity, discomfort in an extremity that worsens with use, and warmth and erythema of the extremity. When a DVT dislodges, it may cause a pulmonary embolism—a blood clot that occludes a portion or all of the pulmonary arteries (**FIGURE 33-30**). Signs and symptoms of a pulmonary embolism include a sudden onset of dyspnea, pleuritic chest pain, tachypnea, tachycardia, right-side heart failure, shock, and, in some cases, cardiac arrest.

In addition to the risk of DVT, patients with long bone or pelvic fractures are at risk for the development of fat embolism syndrome, which occurs when fat globules are released into the bloodstream. In this condition, fat droplets become lodged in the vasculature of the lungs. Affected patients have inflammation of the vasculature of the lungs and other blood vessels where fat is deposited. Generally, symptoms appear between 12 and 72 hours after injury; they include tachycardia, dyspnea, tachypnea, pulmonary congestion, fever, petechiae, change in mental status, and organ dysfunction.

Treatment for fat embolism syndrome in the field is limited to maintaining the airway, adequate oxygenation, and intravascular volume, and rapid transport to an ED.

FIGURE 33-30 When a portion of a deep vein thrombosis dislodges, it may travel to the pulmonary arteries and inhibit blood flow from the heart to the lungs.

Pathophysiology, Assessment, and Management of Specific Injuries

Injuries of the Clavicle and Scapula

The clavicle, or collarbone, is one of the most commonly fractured bones in the body. Fractures of the clavicle occur most often in children when they fall on an outstretched hand. They can also occur with crushing injuries of the chest. A patient with a fracture of the clavicle will report pain in the shoulder and will usually hold the arm across the

front of the body. Young children often report pain throughout the entire arm and are unwilling to use any part of injured limbs. These complaints may make it difficult to localize the point of injury, but, generally, swelling and point tenderness occur over the clavicle (**FIGURE 33-31**). Because the clavicle is subcutaneous (just beneath the skin), the skin will occasionally “tent” over the fracture fragment. The clavicle lies directly over major arteries, veins, and nerves; therefore, fracture of the clavicle may lead to neurovascular compromise, although this is thankfully rare.

Fractures of the scapula, or shoulder blade, occur much less frequently because this bone is well

FIGURE 33-31 A clavicle injury is characterized by swelling, point tenderness, and “tenting” over the fracture fragment.

© American Academy of Orthopaedic Surgeons.

protected by many large muscles. Fractures of the scapula are almost always the result of violent, direct trauma to the back, directly over the scapula, which may also injure the thoracic cage, lungs, and heart. For this reason, you must carefully assess the patient for signs of pneumothorax, hemothorax, and rib fractures. Provide supplemental oxygen and prompt transport for patients who are having respiratory difficulty. The associated chest injuries, not the fractured scapula, pose the greatest threat of long-term disability or death.

Abrasions, contusions, and significant swelling may also occur, and the patient will often limit use of the arm because of pain at the fracture site (**FIGURE 33-32**). The scapula has bony projections that may be fractured with less force.

The joint between the lateral aspect of the clavicle and the acromion process of the scapula is called the acromioclavicular (AC) joint. This joint is frequently separated during football and hockey games when a player falls and lands on the point of the shoulder, driving the scapula away from the outer end of the clavicle. This dislocation is often called an AC separation. The distal end of the clavicle will usually stick out, and the patient will report pain, including point tenderness over the AC joint (**FIGURE 33-33**).

Fractures of the clavicle and scapula and AC separations can all be effectively splinted with a sling and swathe. A **sling** is any bandage or material that helps support the weight of an injured upper extremity, relieving the downward pull of gravity on the injured site. To effectively apply a

FIGURE 33-32 Contusions or abrasions over the scapular area may indicate a fracture.

© American Academy of Orthopaedic Surgeons.

FIGURE 33-33 With acromioclavicular joint separations, the distal end of the clavicle often sticks out.

sling, use gentle upward support to the olecranon process of the ulna (at the elbow). The knot of the sling should be tied to one side of the neck so it does not press uncomfortably on the cervical spine (**FIGURE 33-34A**).

To fully immobilize the shoulder region, a **swathe** (a bandage that passes completely around the chest) must be used to bind the arm to the chest wall. The swathe should be tight enough to prevent the arm from swinging freely but not so tight as to compress the chest and compromise breathing. Leave the patient's fingers exposed so you can assess neurovascular function at regular intervals (**FIGURE 33-34B**).

A

B

FIGURE 33-34 **A.** Apply the sling so the knot is tied to one side of the neck. **B.** Bind the arm to the chest wall with a swathe so the arm cannot swing freely. Leave the patient's fingers exposed so you can assess distal circulation.

Special Populations

A large portion of the older adult population has osteoporosis, or a diminished bone density, that occurs as part of the normal aging process. Women are more susceptible than men to this condition. The presence of osteoporosis increases the likelihood of fractures with even minimal trauma—for example, hip or femur fracture due to a fall from a standing position.

Commercially available shoulder immobilizers or slings provide adequate splinting for injuries of the shoulder region, as will triangular bandage slings.

Dislocation of the Shoulder

The glenohumeral joint (shoulder joint) is where the head of the humerus, the supporting bone of the upper arm, meets the glenoid fossa of the scapula. The glenoid fossa joins with the humeral head to form the glenohumeral joint. It is the most commonly dislocated large joint in the body. Often, the humeral head will dislocate anteriorly, coming to lie in front of the scapula as a result of forced abduction (away from the midline) and external rotation of the arm (**FIGURE 33-35**).

Shoulder dislocations are extremely painful. The patient will guard the shoulder and try to

FIGURE 33-35 Most shoulder dislocations are anterior. Note the absence of the normal rounded appearance of the shoulder.

© E. M. Singletary. Used with permission.

FIGURE 33-36 A patient with a dislocated shoulder will guard the shoulder, trying to protect it by holding the arm in a fixed position away from the chest wall.

© Jones & Bartlett Learning.

protect it by holding the dislocated arm in a fixed position away from the chest wall (**FIGURE 33-36**). The shoulder joint will usually be locked, and the shoulder will appear squared off or flattened. The humeral head will protrude anteriorly underneath the pectoralis major on the anterior chest wall. As a result, the axillary nerve may be compressed, causing a numb patch on the outer aspect of the shoulder. Ensure you document this finding. Some patients may also report some numbness in the hand because of compromise of the nerves or the circulation.

Stabilizing an anterior shoulder dislocation is difficult because any attempt to bring in the arm toward the chest will produce pain. You must splint the joint in whatever position is most comfortable for the patient. If necessary, place a pillow, rolled blankets, or rolled towels between the arm and chest to fill up the space between them (**FIGURE 33-37**). Once the arm is stabilized in this way, the elbow can usually be flexed to a 90° angle without causing further pain. At this point, you can apply a sling to the forearm and wrist to support the weight of the arm. Finally, secure the arm in the sling to the pillow and chest with a swathe. Transport the patient in a sitting or semiseated position.

FIGURE 33-37 Splint the shoulder joint in a position of comfort, and place a pillow or towel between the arm and the chest wall to stabilize the arm, after which the elbow can be flexed to a 90° angle. Apply a sling; secure the arm to the chest with a swathe.

Words of Wisdom

When you are assessing a patient with a possible shoulder dislocation, position yourself behind the patient and compare the shoulders. The dislocated side is usually lower than the uninjured side.

When a shoulder dislocates, it disrupts the supporting ligaments of the anterior aspect of the shoulder. Often these ligaments fail to heal properly, so the dislocation recurs. Each time a dislocation occurs, it may cause further neurovascular compromise and joint injury. In certain cases, surgical repair may be required. Some patients can reduce (set) their own dislocated shoulders. Generally, this occurs in patients who have had multiple shoulder dislocations in the past and are familiar with the maneuver necessary to achieve reduction. For first-time dislocations, this maneuver must typically be done in a hospital setting and only after radiographs have been obtained. The exception is for dislocations that occur in athletic activity where the event was witnessed by a physician and a physician is present to perform the reduction maneuver. In addition, some wilderness EMS providers are trained in dislocation reduction maneuvers,

allowing the patient to self-assist with extrication from the wilderness environment.

A shoulder will dislocate posteriorly instead of anteriorly about once in every 20 cases. Football players, especially linemen, are susceptible to this injury. Dislocations can sometimes be caused by violent seizure activity and these are also often posterior dislocations. The arm will often be locked in an adducted position (toward the midline), so it cannot be rotated. Reducing the dislocation usually requires medical supervision.

Fracture of the Humerus

Fractures of the humerus may occur either proximally, in the midshaft, or distally, at the elbow. Fractures of the proximal humerus resulting from falls are common among older adults. Fractures of the midshaft occur more often in young patients, usually as the result of high-energy injury.

Examine the extremity to reveal any significant swelling, ecchymosis, gross instability of the region, and crepitus. If the force that caused the injury is severe enough, the nerves and blood vessels in the upper arm may also be damaged. Of particular concern is the radial nerve, which may be injured by the force itself or become entrapped within the fracture site. The classic sign of a radial nerve injury is wrist drop.

If the fracture is angulated, longitudinal traction may be applied to correct the deformity, but this effort should be halted if the patient's pain is too severe or if neurovascular status worsens. Once the extremity is in the desired position, apply a rigid splint that extends from the axilla to the elbow. Next, apply a sling and swathe to stabilize the arm to the chest wall (**FIGURE 33-38**), and place cold packs over the fracture site to decrease the patient's pain and swelling. Note: Compartment syndrome can develop in the forearm in children with these fractures.

Elbow Injuries

Fractures and dislocations often occur around the elbow, and the different types of injuries are difficult to distinguish without radiographs (**TABLE 33-4**). However, they all produce similar limb deformities and require the same emergency medical care. Injuries to nerves and blood vessels are quite common in this region. Such injuries can be caused or

FIGURE 33-38 Splint a humeral shaft fracture with a sling and swathe supplemented by a padded board splint on the lateral aspect of the arm.

TABLE 33-4 Types of Elbow Injuries

Type of Injury	Characteristics
Fracture of distal humerus (supracondylar or intercondylar fracture)	- Fracture fragments may rotate significantly, producing deformity and causing injuries to nearby vessels and nerves. - Swelling occurs rapidly and is often severe. - Significant potential for vessel or nerve injury.
Elbow dislocation	- Typically occurs in athletes; rare in young children. - Ulna and radius are most often displaced posteriorly, which makes the olecranon process of the ulna much more prominent (FIGURE 33-39). - Joint is usually locked, making any attempt at motion extremely painful.
Elbow joint sprain	- Rare; usually diagnosed by stress radiographs. - The real problem may be a hard-to-detect fracture.
Fracture of the olecranon process of the ulna	- Usually the result of a direct blow. - Often characterized by lacerations and abrasions. - Patient may be unable to extend the elbow.
Fracture of the radial head	- Results from a fall on an outstretched arm or a direct blow to the lateral aspect of the elbow. - Attempts to rotate the elbow and wrist cause severe discomfort.

worsened by inappropriate emergency medical care, particularly by excessive manipulation of the injured joint.

Special Populations

Toddlers can sustain an injury similar to an elbow dislocation when they are lifted or pulled by the arm. This injury, which is sometimes called nursemaid's elbow, is a soft-tissue impingement condition, not a joint dislocation.

Care of Elbow Injuries

Like any joint injury, elbow injuries are serious and require careful management. Always assess distal neurovascular functions periodically in patients with elbow injuries. If you find strong pulses and good capillary refill, splint the elbow in the position in which you found it, adding a wrist sling if this seems helpful. Two padded board splints, applied to each side of the limb and secured with soft roller bandages, usually are enough to stabilize the arm (**FIGURE 33-40A**). Ensure the board extends from the shoulder joint to the wrist joint, stabilizing the entire bone above and below the injured joint. Alternatively, you can mold a padded wire ladder splint or a SAM splint to the shape of the limb (**FIGURE 33-40B**). If necessary, you may add further support to the limb with a pillow.

A cold, pale hand or a weak or absent pulse and poor capillary refill indicate the blood vessels

A

B

FIGURE 33-40 **A.** Two padded board splints provide adequate stabilization for an injured elbow. **B.** A structural aluminum malleable splint can be molded to the shape of the limb so you can splint it in the position in which it was found.

have likely been injured. Further care of this patient must be dictated by a physician. Consult medical direction immediately. If you are within 15 minutes of the hospital, splint the limb in the position in which you found it and provide prompt transport. Otherwise, consult medical direction to guide you in trying to realign the limb to improve circulation in the hand.

If the limb is pulseless and significantly deformed at the elbow, then apply gentle manual traction in line with the long axis of the limb to decrease the deformity. This maneuver may restore the pulse. Excessive manipulation will only worsen the vascular problem. If no pulse returns after one attempt, splint the limb in the most comfortable position for

the patient. If the pulse is restored by gentle realignment, splint the limb in whatever position allows the strongest pulse. Provide prompt transport for all patients with impaired distal circulation.

Special Populations

Epiphyseal (growth) plate injuries in children are common, especially around the wrist, elbow, knee, and ankle. Injuries tend to occur through these cartilaginous growth centers because they are inherently weaker than the surrounding bone. Because longitudinal growth of the limb is dependent on the function of the growth plate, it is extremely important to recognize the possibility of growth plate injuries, stabilize the injured limb, and transport the patient in a timely manner to an appropriate center with pediatric orthopaedic coverage. Proper functioning of the injured growth plate throughout the remainder of skeletal growth may depend on timely anatomic reduction of the fracture and close follow-up by an orthopaedic surgeon.

Assume any deformity in proximity to a joint in children younger than 16 years is a growth plate injury. The child should be transported and treated appropriately.

Fractures of the Forearm

Fractures of the shaft of the radius and ulna are common in people of all age groups, but are seen most often in children and older adults. Usually, both bones break at the same time when the injury is the result of a fall on an outstretched hand (**FIGURE 33-41**). An isolated fracture of the shaft of the ulna may occur as the result of a direct blow to it—an injury known as a nightstick fracture.

Fractures of the distal radius, which are especially common in older adult patients with osteoporosis, are often known as Colles fractures. The term *silver fork deformity* is used to describe the distinctive appearance of the patient's arm (**FIGURE 33-42**). In children, this fracture may occur through the growth plate (**FIGURE 33-43**) and can sometimes have long-term consequences.

To stabilize fractures of the forearm or wrist, you can use a padded board, air, vacuum, or pillow

FIGURE 33-41 Fractures of the forearm often occur in children as a result of a fall on an outstretched hand.

splint. If the shaft of the bone has been fractured, ensure you include the elbow joint in the splint. Splinting of the elbow joint is not essential with fractures near the wrist; however, the patient will be more comfortable if you add a sling or pillow for more support. If possible, elevate the injured extremity above the heart to help alleviate swelling.

Injuries of the Wrist and Hand

Injuries of the wrist, ranging from dislocations to sprains, must be confirmed by radiographs. Dislocations are usually associated with a fracture, resulting in a fracture-dislocation. Another common wrist injury is the isolated, nondisplaced fracture of a carpal bone, especially the scaphoid. Any questionable wrist sprain must be splinted and evaluated in the ED or an orthopaedic surgeon's office.

Hand injuries vary widely, and some have potentially serious consequences. Dislocations, fractures, lacerations, burns, and amputations occur in industrial, recreational, and home accidents. Because the fingers and hands are required to function in such intricate ways, any injury that is not treated properly may result in permanent disability and deformity. For this reason, all injuries to the hand, including simple lacerations, must be evaluated promptly by a physician. Do not attempt to “pop” a dislocated finger joint back into place.

Always take any amputated parts to the hospital with the patient. Ensure you wrap the amputated part in a dry or moist sterile dressing, depending on your local protocol, and place it in a dry plastic bag. Put the bag in a cooled container; *do not* soak the part in water or allow it to freeze.

A bulky forearm dressing makes an effective splint for any hand or wrist injury. Once the injury is splinted, apply a sling and swathe or prop the splinted hand and wrist on a pillow or on the patient's chest during transport to the hospital. To splint the hand and wrist, follow the steps in

SKILL DRILL 33-7.

Fractures of the Pelvis

Pelvic fractures are relatively uncommon injuries, accounting for approximately 3% of all fractures.⁷ Despite the low incidence, these injuries are responsible for a significant number of deaths in blunt

trauma patients. The risk of death following a pelvic fracture ranges from 19% to 50% in older adult patients,⁸ and from 3% to 20% overall,⁷ depending on the severity of the injury; when the fracture is open, the mortality rate rises to as high as 50%.⁹ Usually, death after a pelvic fracture results from massive hemorrhage caused by damage to the arteries and veins of the pelvis.

Disruptions of the pelvic ring occur secondary to high-energy trauma such as crush injuries, motorcycle crashes, and falls from a significant height. Many structures within the pelvis are at risk for injury when it is fractured: the bladder, urethra, rectum, vagina, and sacral nerve plexus. The blood vessels that are most prone to damage are the veins within the pelvis, but there may be damage to the internal or external iliac arteries and arteries in the lumbar region. The nerves at greatest risk of injury are those in the lumbar and sacral regions and the sciatic and femoral nerves. In addition, if a woman who is pregnant experiences a pelvic fracture, her fetus may be injured.

Fractures of the pelvis may be accompanied by a life-threatening loss of blood from the laceration of blood vessels affixed to the pelvis at certain key points. Up to several liters of blood may drain into the pelvic space and the **retroperitoneal space**, which lies between the abdominal cavity and the posterior abdominal wall. The result is significant hypotension, shock, and sometimes death. Therefore, take immediate steps to treat shock, even if there is only minimal swelling. Often, there are no visible signs of bleeding with a pelvic fracture until severe blood loss has occurred. Be prepared to resuscitate the patient rapidly if this becomes necessary.

Patients with pelvic ring disruptions who have a stable injury, such as a minimal lateral compression injury, may report pain in the pelvis and difficulty bearing weight. Patients with a more severe injury may show evidence of profound shock, gross pelvic instability, and diffuse pelvic and lower abdominal pain. There may also be bruising or lacerations in the perineum, scrotum, groin, suprapubic region, and flank, and hematuria (blood in the urine) or blood coming from the meatus of the penis, vagina, or rectum.

Specific types of fractures are discussed in the next sections.

Skill Drill 33-7 Splinting the Hand and Wrist

Step 1

Take standard precautions and cover open wounds with a dry, sterile dressing. Assess pulse and motor and sensory function. Support the injured limb, and move the hand into the position of function. Place a soft roller bandage in the palm of the patient's injured hand.

Step 2

Apply a padded board splint on the palmar side of the wrist, leaving the fingers exposed.

Step 3

Secure the entire length of the splint with a soft roller bandage. Apply a sling and swathe or prop the splinted hand and wrist on a pillow or on the patient's chest during transport.

Lateral Compression Pelvic Ring Disruptions

Lateral compression injuries result from an impact on the side of the body (such as being struck by a motor vehicle from the side or falling from a significant height and landing on one side of the body).

The side of the pelvis that sustains the impact becomes internally rotated around the sacrum, and the actual volume within the pelvis decreases (**FIGURE 33-44**). Although this injury does not commonly cause massive hemorrhage into the pelvis, it is often associated with injuries in other regions of the body.

FIGURE 33-44 **A.** A lateral compression injury to the pelvis. **B.** A radiograph of a lateral compression injury.

A: © Jones & Bartlett Learning; **B:** Courtesy of Andrew N. Pollak, MD, FAAOS.

Anterior-Posterior Compression Pelvic Ring Disruptions

Anterior-posterior compression pelvic ring disruptions may occur following a head-on MVC, motorcycle crash, fall, or when a pedestrian is struck head-on by a motor vehicle. The force of the impact compresses the pelvis in the anterior-to-posterior direction, causing the pubic symphysis and posterior supporting ligaments to be disrupted and tear apart. The pelvis then spreads apart and opens like a book, hence the name **open book pelvic fracture**. Such an injury has the potential for massive blood

loss because the volume of the pelvis is greatly increased.

Vertical Shear

Vertical shear injuries occur when a major force is applied to the pelvis from above or below, such as when a person falls from a significant height and lands on the feet. On landing, the force is transmitted through the legs to the pelvis, leading to the complete displacement of one or both sides of the pelvis toward the head. Thus, this kind of injury has anterior and posterior components. The anterior

component involves a fracture of the rami or disruption of the symphysis pubis. The posterior component involves a fracture of the ilium or sacrum or a disruption of the sacroiliac joint. The patient is likely to have significant shortening of the limb on the affected side and is at risk for massive hemorrhage into the pelvis.

Straddle Fracture

A **straddle fracture** occurs after a fall when a person lands in the region of the perineum and sustains bilateral fractures of the inferior and superior rami. This injury does not interfere with weight bearing, but it does carry a risk because of its associated complications, particularly those of the lower genitourinary system.

Open Pelvic Fractures

Open pelvic fractures are life-threatening injuries. Such an injury is defined by the presence of a laceration of the skin in the pelvic region, vagina, or rectum. This uncommon fracture is caused by a high-velocity injury with subsequent massive hemorrhage. Even small amounts of blood found during a vaginal or rectal exam should raise your suspicion for an open fracture.

Care of Pelvic Fractures

You should suspect a fracture of the pelvis in any patient who has sustained a high-velocity injury

Special Populations

A hip fracture in an older adult patient can be a debilitating and life-altering injury. In many cases, these injuries occur in the home after slipping on a throw rug, tripping over an object that extends into the walkway, or stumbling because of poor lighting. To help prevent this injury and other fall-related problems, you should point out any safety hazards in the home to the patient or a family member. It takes only a minute, and most patients and families appreciate the advice.

and experiences discomfort in the lower back or abdomen. Because large muscles and other soft tissues cover the area, deformity or swelling may be difficult to see. The most reliable sign of a fracture of the pelvis is simple tenderness on firm compression and palpation. Firm compression on the two iliac crests will produce pain at a fracture site in the pelvic ring. Assess for tenderness by taking the following steps (**FIGURE 33-45**):

1. Place the palms of your hands over the lateral aspect of each iliac crest, and apply firm but gentle inward pressure on the pelvic ring.
2. With the patient lying supine, place a palm over the anterior aspect of each iliac crest, and apply firm downward pressure.
3. Use the palm of your hand to firmly but gently palpate the pubic symphysis, the firm

FIGURE 33-45 **A.** To assess for tenderness in the pelvic region, place your hands over the lateral aspect of each iliac crest, and gently compress the pelvis. **B.** With the patient in a supine position, place your palms over the anterior aspect of each iliac crest, and apply firm but gentle downward pressure. **C.** Palpate the pubic symphysis with the palm of your hand.

cartilaginous joint between the two pubic bones. This area will be tender if there is injury to the anterior portion of the pelvic ring.

Once you have identified significant tenderness or any instability, further pressure on the pelvis for the purposes of examination is contraindicated as it could potentially result in worsening hemorrhage or injury by displacing fracture fragments or blood clots that have formed over bleeding veins or arteries. Do not manipulate this area during reassessments.

If there has been injury to the bladder or the urethra, the patient will have lower abdominal tenderness and may have evidence of **hematuria** (blood in the urine) or blood at the urethral opening.

Perform a primary survey, and carefully monitor the general condition of any patient you suspect has a pelvic fracture, because the patient is at high risk for hypovolemic shock.

Treatment should include careful monitoring of the ABCs, spinal immobilization, and IV access with at least one large-bore catheter, if not two. Managing a pelvic injury involves reducing the amount of bleeding and decreasing the degree of instability. It is often appropriate to seek medical direction to manage these patients, especially to determine how to best stabilize the pelvis. Methods used to accomplish this stabilization may include application of a PASG or pelvic binder or simply tying a sheet around the pelvis at the level of the femoral trochanters and pubic symphysis. This reduces the potential space within the pelvis, which may allow for tamponade of the bleeding vessels. Once immobilized on a long backboard, the patient should be rapidly transported to a trauma center, and IV fluid should be administered to maintain adequate tissue perfusion (radial pulses) yet avoid hypertension, which may increase internal hemorrhage.

Words of Wisdom

Consider ways to avoid log rolling a patient with pelvic pain. If the pain is on one side, log roll to the other side to avoid discomfort. If the pain is bilateral and time allows, use a scoop stretcher to move the patient onto a backboard, or simply use the scoop stretcher to immobilize the patient. Try to avoid causing unnecessary discomfort to the patient by paying attention to complaints of pain and your findings in the secondary survey.

Dislocation of the Hip

The hip joint is a highly stable ball-and-socket joint that is dislocated only after significant injury. Almost all dislocations of the hip are posterior; that is, the femoral head is displaced posteriorly to lie in the muscles of the buttock. Posterior dislocation of the hip most commonly occurs during MVCs in which the knee meets with a direct force, such as the dashboard, and the entire femur is driven posteriorly, dislocating the joint (**FIGURE 33-46**). Thus, suspect a hip dislocation in any patient who has been in an MVC and has a contusion, laceration, or obvious fracture in the knee region. Rarely does the femoral head dislocate anteriorly; in this circumstance, the legs are suddenly and forcibly spread wide apart and locked in this position.

Posterior dislocation of the hip is frequently complicated by injury to the sciatic nerve, which is located directly behind the hip joint. The **sciatic nerve** is the most important nerve in the lower extremity; it controls the activity of muscles in the posterior thigh and below the knee, as well as sensation in the entire leg and foot. When the head of the femur is forced out of the hip socket, it may compress or stretch the sciatic nerve, leading to partial or complete paralysis of the nerve. The result

FIGURE 33-46 Posterior dislocation of the hip can occur as a result of the knee hitting the dashboard in a motor vehicle crash. The impact drives the femur posteriorly (see arrow), dislocating the joint.

© Jones & Bartlett Learning.

is decreased sensation in the leg and foot and, frequently, weakness in the foot muscles. Generally, only the dorsiflexors (the muscles that raise the toes or foot) are involved, causing the foot drop that is characteristic of damage to the portion of the sciatic nerve that controls the muscles in the anterior and lateral compartments of the leg, particularly those that control ankle dorsiflexion.

Patients with a posterior dislocation of the hip typically lie with the hip joint flexed (the knee joint drawn up toward the chest) and the thigh rotated inward toward the midline of the body over the top of the opposite thigh (**FIGURE 33-47A**). With the less-common anterior dislocation, the limb is in the

A

B

FIGURE 33-47 A. The usual position of a patient with a posterior dislocation of the hip. The hip joint is flexed, and the thigh is rotated inward and adducted across the midline of the body. **B.** Support the affected limb with pillows and blankets, particularly under the flexed knee. Secure the entire limb to a scoop stretcher or long backboard with long straps to prevent movement during transport.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

opposite position, extended straight out, rotated, and pointing away from the midline of the body.

Dislocation of the hip is associated with distinctive signs. The patient will have severe pain in the hip and will strongly resist any attempt to move the joint. The lateral and posterior aspects of the hip region will be tender on palpation. With some people who are thin, you can palpate the femoral head deep within the muscles of the buttock. Check for a sciatic nerve injury by carefully assessing sensation and motor function in the lower extremity. Occasionally, sciatic nerve function will be normal at first and then slowly diminish.

As with any other extremity injury, do not attempt to reduce the dislocated hip in the field. Splint the dislocation in the position of the deformity and place the patient supine on a scoop stretcher or long backboard. Support the affected limb with pillows and rolled blankets, particularly under the flexed knee (**FIGURE 33-47B**). Then secure the entire limb to the backboard with long straps so the hip region will not move. Provide prompt transport.

Words of Wisdom

When you find a knee injury in the victim of an MVC, especially one in the front seat, look for posterior dislocation of the hip.

Fractures of the Proximal Femur

Fractures of the proximal (upper) end of the femur are among the most common fractures, especially in older adults. Although they are usually called hip fractures, they rarely involve the hip joint. Instead, the break goes through the neck of the femur, the intertrochanteric (middle) region, or across the proximal shaft of the femur (subtrochanteric fractures). Although these three fracture types occur most often in older adult patients, particularly patients with osteoporosis, they may also be seen as a result of high-energy injuries in young patients.

Patients with displaced fractures of the proximal femur display a characteristic deformity. They lie with the leg externally rotated, and the injured leg is usually shorter than the opposite, uninjured limb (**FIGURE 33-48A**). When the fracture is not displaced, this deformity is not present. With any kind of hip fracture, patients typically are unable to walk

or move the leg because of pain in the hip region or in the groin or inner aspect of the thigh. The hip region is usually tender on palpation, and gentle rolling of the leg will cause pain but will not do further damage. On occasion, the pain is referred to the knee, and it is not uncommon for an older adult patient with a hip fracture to complain of knee pain after a fall.

You should assess the pelvis for any soft-tissue injury and bandage appropriately. In addition,

assess pulses and motor and sensory functions, looking for signs of vascular and nerve damage. Once you complete your assessment, splint the lower extremity of an older adult patient who has fallen and reports pain in the hip or the knee, even if there is no deformity, and then transport the patient to the ED.

The age of the patient and the severity of the injury will dictate how you splint the fracture. A geriatric patient with an isolated hip fracture does

A

B

FIGURE 33-48 **A.** A patient with a fracture of the proximal femur will typically lie still with the extremity rotated, making the injured leg appear shorter than the other leg. **B.** Splint the injured leg to the uninjured leg or to the backboard, and secure the patient on a scoop stretcher or long backboard.

YOU are the Provider

Part 4

Approximately 35 minutes into your transport, the patient begins to report searing pain to his femoral area and numbness and tingling in his left foot. You examine the area and find that the area around his femur is very firm, and he has decreased sensation in his left foot. You know this is an important finding, so you call the trauma center and report your findings. The physician on call states it sounds as if compartment syndrome may be developing. After discussing care with the physician on call, your partner informs you that you are 8 minutes from the hospital and you begin to prepare the patient for removal from the ambulance. On arrival at the hospital, you wheel the patient into the trauma bay and turn over his care to the awaiting trauma surgeon.

Recording Time: 45 Minutes

Respirations	22 breaths/min, clear
Pulse	127 beats/min
Skin	Cool, pale, and clammy
Blood pressure	96/44 mm Hg
Oxygen saturation (SpO₂)	98% on 15 L/min
Pupils	PERRLA

7. Which signs and symptoms may suggest compartment syndrome?
8. What should your treatment of compartment syndrome include?

not require a traction splint. You can effectively immobilize such a fracture by placing the patient on a long backboard or scoop stretcher, using pillows or rolled blankets to support the injured limb in the deformed position, then securing the injured limb carefully to the uninjured limb or to the backboard (**FIGURE 33-48B**).

All patients with hip fractures may have significant blood loss. Therefore, administer oxygen as needed and frequently monitor vital signs, being alert for signs of shock. Initiate IV therapy and give a 20-mL/kg bolus of an isotonic crystalloid solution, repeating as necessary to maintain radial pulses.

Femoral Shaft Fractures

Fractures of the femur can occur in any part of the shaft, from the hip region to the femoral condyles just above the knee joint. Following a fracture, the quadriceps muscles begin to spasm and often produce significant deformity of the limb, with severe angulation or external rotation at the fracture site. Usually the limb shortens significantly as well. Fractures of the femoral shaft are occasionally open, and fragments of bone may protrude through the skin. As with any other open fracture, do not attempt to push the bones back into the skin.

Patients often experience significant blood loss (perhaps 500 to 1,500 mL) at the fracture site. In addition, damage to the neurovascular structures of the thigh is possible. Continue to watch for the onset of hypovolemic shock. Provide immediate transport in this situation.

Cover any wound with a dry, sterile dressing. If the foot or leg below the level of the fracture shows signs of impaired circulation (is pale, cold, or pulseless), apply gentle longitudinal traction to the deformed limb in line with the long axis of the limb. Gradually turn the leg from the deformed position to restore the limb's overall alignment. Often, this action restores or improves circulation to the foot. If it does not, the patient may have sustained a serious vascular injury and needs prompt medical attention.

Managing femoral shaft fractures includes monitoring for evidence of shock, full spinal immobilization, and establishing vascular access. Place the injured extremity in a traction splint or use a PASG to achieve stability and hemorrhage control. Because these injuries may be extremely painful,

consider calling for paramedic backup to administer pain medication if it will not delay transport to a trauma center.

Knee Injuries

The knee is extremely susceptible to injury; therefore, many different types of injuries occur in this region. Ligament injuries, for example, range from mild sprains to complete dislocation of the joint. The patella can also dislocate. In addition, all bony elements of the knee (distal femur, upper tibia, and patella) can fracture. Assess the patient's knee to reveal any significant pain in the knee, decreased range of motion, pain with movement and weight bearing, ecchymosis, swelling, and, in the case of displaced fractures, deformity.

Injuries of Knee Ligaments

The knee is especially susceptible to ligament injuries, which occur when abnormal bending or twisting forces are applied to this joint. Such injuries are often seen in both recreational and competitive athletes. The ligaments on the medial side of the knee are the ones that are most frequently injured, typically when the foot is fixed to the ground and a heavy object strikes the lateral aspect of the knee, such as when a football player is clipped or tackled from the side.

Dislocation of the Knee

A dislocated knee is a true emergency that may threaten the limb. When the knee is dislocated, the ligaments that provide support to it may be damaged or torn. When this happens, the proximal end of the tibia is completely displaced from its juncture with the lower end of the femur, usually producing a significant deformity. Although substantial ligament damage always occurs with a knee dislocation, the more urgent injury is to the popliteal artery, which is often lacerated or compressed by the displaced tibia. When gross deformity, severe pain, and an inability to move the joint cause you to suspect a dislocation of the knee, always check the distal circulation carefully before taking any other step. If the distal pulses are absent, contact medical direction immediately for further stabilization instructions.

The direction of dislocation refers to the position of the tibia with respect to the femur. Anterior

knee dislocations, which result from extreme hyperextension of the knee, are the most common, occurring in almost one-half of all cases. Commonly, the anterior and posterior ligaments are damaged, but there is also a high risk of injury to the popliteal artery.

In posterior dislocations, a direct blow to the knee forces the tibia to shift posteriorly. There is also the possibility of damage to the ligaments. These dislocations are associated with the highest degree of risk to the popliteal artery.

Medial dislocations result from a direct blow to the lateral part of the leg. Because the deforming force causes the medial aspect of the knee to stretch apart, there is a high likelihood of injury to the medial ligaments. When the force is applied from the medial direction, a lateral dislocation occurs and the lateral part of the knee is stretched apart, injuring the lateral ligament. Lateral and medial dislocations happen less commonly and are less likely to injure the popliteal artery.

Patients with a knee dislocation will typically report pain in the knee and report that the knee “gave out.” If the knee did not spontaneously reduce, there may be evidence of significant deformity and decreased range of motion. Complications may include limb-threatening popliteal artery disruption, injuries to the nerves, and joint instability. Do not confuse this injury with a relatively minor patellar dislocation.

If adequate distal pulses are present, splint the knee in the position in which you found it, and promptly transport the patient. Do not attempt to manipulate or straighten any severe knee injury if there are good distal pulses. If the limb is straight, then apply leg splints to both sides of the limb to immobilize it (**FIGURE 33-49A**). If the knee is bent and the foot has a good pulse, then splint the joint in the bent position, using parallel padded board splints secured at the hip and ankle joint to provide a stable A-frame (**FIGURE 33-49B**). Secure the limb to a backboard or stretcher with pillows and straps to eliminate any motion during transport.

On rare occasions, medical direction may instruct you to realign a deformed, pulseless limb to reduce compression of the popliteal artery, thereby restoring distal circulation. You should make only one attempt to do this. First, straighten the limb by applying gentle longitudinal traction in the axis of the limb. Maintain stability until the limb is fully

A

B

FIGURE 33-49 A. When the injured knee is straight, apply padded board splints extending from the hip to the ankle. **B.** If the knee is flexed and the foot has good pulses, apply padded board splints with the knee in the flexed position.

© Jones & Bartlett Learning.

splinted. If manipulation significantly increases the patient's pain, do not continue. As you straighten the leg, monitor the posterior tibial pulse to see whether it returns. Splint the limb in the position in which you feel the strongest pulse. If you are unable to restore the distal pulse, then splint the limb in the position that is most comfortable for the patient, and then provide prompt transport to the hospital.

Notify medical direction of the status of the distal pulse so arrangements to treat the patient can be made in advance.

Fractures About the Knee

Fractures about the knee may occur at the distal end of the femur, at the proximal end of the tibia, or in the patella. Because of local tenderness and swelling, it is easy to confuse a nondisplaced or minimally displaced fracture about the knee with a ligament injury. Likewise, a displaced fracture about the knee may produce significant deformity that makes it look like a dislocation.

How you manage a knee fracture will depend on the position of the leg and the status of distal pulses. If the patient has a good distal pulse, then splint the extremity in the position in which it is found. If there is no distal pulse, then seek medical consultation to determine whether you should attempt manipulation before transportation. In all cases, elevate the leg to the heart level and apply cold packs. Frequent neurovascular checks are mandatory, given the high incidence of compartment syndrome and neurovascular injury in cases of knee fracture. Continue to monitor the distal neurovascular function en route to the hospital.

Dislocation of the Patella

A dislocated patella most commonly occurs in teenagers and young adults who are engaged in athletic activities. Some patients have recurrent dislocations of the patella. As with recurrent dislocation of the shoulder, minor twisting may be enough to produce the problem. The displacement of the patella produces a substantial deformity in which the knee is held in a slightly flexed position and the patella is displaced to the lateral side of the knee (**FIGURE 33-50**).

Splint the knee in the position in which you found it. Most often, this position involves the knee being flexed to a moderate degree. To immobilize the knee, apply padded board splints to the medial and lateral aspects of the joint, extending from the hip to the ankle. Use pillows to support the limb on the stretcher.

Occasionally, as you apply the splint, the patella will spontaneously return to its normal position. When this occurs, stabilize the limb as you would for any knee injury, in a padded long leg splint.

FIGURE 33-50 Usually, a dislocated patella displaces to the lateral side, and the knee is held in a partially flexed position.

© Life in the Fast Lane. Accessed at: <https://lifeinthefastlane.com>

The patient still needs to be transported to the ED. Report the spontaneous reduction as soon as you arrive at the hospital so the medical staff is aware of the severity of the injury.

Injuries of the Tibia and Fibula

The tibia (shinbone) is the larger of the two leg bones that are responsible for supporting the major weight-bearing surface of the knee and ankle; the fibula is the smaller of them. Fractures of the shaft of the tibia or the fibula may occur at any place between the knee joint and the ankle joint. Usually both bones fracture at the same time (**FIGURE 33-51**). Even a single fracture may result in severe deformity, with significant angulation or rotation. Because the tibia is located just beneath the skin, open fractures of this bone are common (**FIGURE 33-52**).

Fractures of the tibia and fibula should be stabilized with a padded, rigid long leg splint or an air splint that extends from the foot to the upper thigh. Once splinted, the affected leg should be secured to the opposite leg. As with most other fractures of the shaft of long bones, you should correct a severe deformity before splinting by applying gentle

FIGURE 33-51 Open tibia and fibula fracture.

© American Academy of Orthopaedic Surgeons.

FIGURE 33-52 Because the tibia is so close to the skin, open fractures are common.

© American Academy of Orthopaedic Surgeons.

longitudinal traction. The goal is to restore a position that will take a standard splint; it is not necessary to replace the fracture fragments in their anatomic position.

Fractures of the tibia and fibula are sometimes associated with vascular injury as a result of the distorted position of the limb following injury. Realigning the limb may restore adequate blood supply to the foot. If it does not, transport the patient promptly and notify medical direction while you are en route.

Ankle Injuries

Ankle fractures usually result from sudden, forceful movements of the foot that damage the malleoli and sometimes produce dislocation (called a

FIGURE 33-53 Swelling about the ankle is characteristic of both sprains and fractures.

© rob_lan/iStock/Getty Images.

FIGURE 33-54 Apply cold packs to ankle injuries, and splint with the foot in the position of function. Remember to check the distal pulse.

© Courtesy of Rhonda Hunt.

fracture-dislocation). In other cases, an axial load is transmitted through the foot and causes the talus (the bone of the foot that articulates with the tibia) to impact the distal tibia, leading to a fracture.

Signs and symptoms of an ankle fracture include pain, deformity, and swelling (**FIGURE 33-53**). Ankle fractures may lead to damage of the nerves and blood vessels that supply the foot, the development of compartment syndrome, and chronic ankle pain and arthritis.

Stabilize ankle fractures using a commercially available splint or a pillow splint. Leave the toes exposed to allow for frequent checks of distal neurovascular function. Elevate the extremity to the heart level, and apply cold packs to reduce swelling (**FIGURE 33-54**).

If an ankle fracture-dislocation is associated with a pulseless foot, then medical direction may recommend that you attempt reduction. To reduce a fracture-dislocation of the ankle, first relax the calf muscle by flexing the patient's leg at the knee to allow the foot to move more freely. With the leg flexed, grasp the heel and the foot just proximal to the toes and apply gentle traction. Next, rotate the foot back into its normal position without forcing it. If this procedure is successful, reassess the distal neurovascular status and splint the extremity in the reduced position, using care not to allow the ankle to dislocate again. If you are unable to reduce the fracture-dislocation, then notify medical direction, splint the ankle in the position it was found, and provide rapid transport.

Foot Injuries

Injuries to the foot can result in the fracture of one or more of the tarsals, metatarsals, or phalanges of the toes. Toe fractures are especially common.

Of the tarsal bones, the calcaneus, or heel bone, is the most frequently fractured. Injury usually occurs when the patient falls or jumps from a height and lands directly on the heel. The force of injury compresses the calcaneus, producing immediate swelling and ecchymosis. If the force of impact is great enough, such as from a fall off a roof or out of a tree, there may be other fractures as well.

Frequently, the force of injury is transmitted up the legs to the spine, producing a fracture of the lumbar spine (**FIGURE 33-55**). When a patient who has jumped or fallen from a height reports heel pain, ensure you ask the patient about any back pain and carefully assess the spine for tenderness or deformity.

If you suspect that the foot is dislocated, immediately assess the patient's pulses and motor and sensory function. If pulses are present, immobilize the extremity using a commercially available splint or a pillow splint, leaving the toes exposed so you can periodically assess neurovascular function. If pulses are absent, consult medical direction and discuss reduction of the dislocation if local protocols permit.

Injuries of the foot are associated with significant swelling but rarely with gross deformity. Vascular injuries are not common. As in the hand, lacerations of the ankle and foot may damage

FIGURE 33-55 Frequently, the force of injury after a fall is transmitted up the legs to the spine, sometimes resulting in a fracture of the lumbar spine.

© Jones & Bartlett Learning.

important underlying nerves and tendons. Puncture wounds of the foot are common and may cause serious infection if not treated early. These injuries must be evaluated and treated by a physician.

To splint the foot, apply a rigid padded board splint, an air splint, or a pillow splint, stabilizing the ankle joint as well as the foot (**FIGURE 33-56**). Leave the toes exposed so you can periodically assess neurovascular function.

When the patient is lying on the stretcher, elevate the foot approximately 6 inches (15 cm) to minimize swelling. All patients with lower extremity injuries should be transported in the supine position to allow for elevation of the limb. Never allow the foot and leg to dangle off the stretcher onto the floor or ground.

If a patient has fallen from a height and reports heel pain, then use a long backboard to stabilize any possible spinal injury in addition to splinting the foot.

FIGURE 33-56 A pillow splint provides excellent stabilization of the foot and ankle.

Amputations

Surgeons can often reattach amputated parts. However, correct prehospital care of the amputated part is vital to successful reattachment. With partial amputations, ensure you immobilize the part with bulky compression dressings and a splint to prevent further injury. Do not sever any partial amputations, as this may complicate later reattachment.

Hemorrhage from complete or incomplete amputations can be severe and life threatening. You must control bleeding and treat for shock when dealing with amputations. Control any bleeding to the stump. If bleeding cannot be controlled, then quickly apply a **tourniquet** just above the site of the amputation. Complete traumatic amputations may not bleed much because the cut vessels may spasm, preventing the bleeding.

Make every attempt to preserve an amputated part in optimal condition to maximize the chances of it being successfully reimplanted. With

a complete amputation, wrap the amputated part in a sterile dressing and place it in a plastic bag. Follow your local protocols regarding how to preserve amputated parts. In some areas, dry sterile dressings are recommended for wrapping amputated parts; in other areas, dressings moistened with sterile saline are recommended. Put the plastic bag in a cool container filled with ice water. Float the bag containing the wrapped part on a bed of ice water; do not pack it in ice, and never lay the wrapped part directly onto the ice. The goal is to keep the part cool without allowing it to freeze or for frostbite to develop. Do not warm an amputated part or place an amputated part in water. Rapidly transport the patient with the amputated part to the appropriate facility.

When the amputated part is a limb or part of a limb, notify the ED staff in advance of the type of case you are transporting and your estimated time of arrival so a surgical team can be mobilized while you are en route. Consider administering a bolus of an isotonic crystalloid solution if the patient has experienced significant blood loss or is hypotensive.

Finally, be aware of the patient's emotional stress, which can lead to psychogenic shock. Amputations are discussed in more detail in Chapter 28, *Soft-Tissue Injuries*.

Sprains and Strains

Because it may be difficult to differentiate among the various types of injuries in the field, it is best to err on the side of caution and treat every severe sprain as if it were a fracture. General treatment of sprains is similar to the treatment of fractures and includes the following components (numbers 1 through 5 form the RICES mnemonic):

1. **Rest** (Immobilize or splint the injured area.)
2. **Ice** or cold pack over the injury
3. **Compression** with an elastic bandage (usually applied at the hospital once radiography rules out a fracture)
4. **Elevation**
5. **Splinting**
6. Reduced or protected weight bearing
7. Pain management as soon as practical

Strains are treated the same way as sprains.

YOU are the Provider SUMMARY

1. How should you prepare this patient for transport?

You know this patient could have a pelvic fracture and a femur fracture, so take steps to immobilize these fractures. This includes ensuring adequate and appropriate IV access and splinting. Splinting of the pelvis may be accomplished by various methods, according to local protocols, but should include applying a pelvic binder, or simply tying a sheet around the pelvis for stabilization. Failure to properly immobilize these injuries may result in significant internal bleeding for the patient as well as an increase in pain.

2. What should you do when advanced modes of transport are not available?

Transport patients in critical condition according to your local protocols. This patient requires rapid transport to a trauma center capable of orthopaedic surgery. Fractures such as these often result in severe pain, which paramedics can treat with the administration of narcotics. In this scenario, the flight crew is unavailable; likewise, no paramedics are available in the area. Treatment of this patient en route will, for the most part, be supportive.

3. What is the potential blood loss in a femur fracture? Pelvic fracture?

Blood loss from a femur fracture can be life threatening or minor, depending on the severity of the fracture and extent of pelvic displacement. Blood loss from a femur fracture can be as much as 1,000 mL to 1,500 mL; for a pelvic fracture, the loss can be 3,000 mL or more. Thus, a patient with a pelvic fracture is predisposed to hypovolemic shock as well as the potential for exsanguination.

4. Should this patient have a second IV line initiated?

This patient requires a second IV line, depending on local protocols. Given his potential for significant blood loss, rapid administration of IV fluid may be required en route as well as administration of blood products at the receiving facility. By having a second IV line in place, the AEMT can ensure the correct amount of fluid is administered to this patient in a timely manner.

5. What are some potential complications of femur and pelvic fractures?

Pelvic fractures can cause injuries to all the structures that occupy the pelvic cavity. Injuries are often

seen in the urinary bladder, urethra, and rectum. Injuries to the weight-bearing area of the hip joint within the pelvis can lead to early arthritis.

Significant bleeding can result if the rich blood supply to the femur and surrounding muscle is disrupted after fracture. Shock, anemia, and injury to the sciatic nerve or the superficial femoral artery or other veins may occur.

6. What are the considerations when using lactated Ringer solution with trauma patients?

Traumatic injuries, especially crush injuries, may result in the buildup of toxins. The primary substances that are of concern are lactic acid, potassium, and myoglobin. Patients may also experience rhabdomyolysis and hyperkalemia from muscle breakdown. Because lactated Ringer solution contains potassium and other components, it is better to use normal saline if a crush injury or compartment syndrome is suspected. Remember, blood products are incompatible with lactated Ringer solution. For this reason, if you are starting an IV line on a patient with multisystem trauma whom you suspect will require a blood transfusion, always have an IV line of normal saline.

7. Which signs and symptoms may suggest compartment syndrome?

Compartment syndrome is characterized by severe pain that is localized to the involved compartment and out of proportion to the injury. This pain is typically not relieved with pain medication, including narcotics. As time progresses, the affected area may feel very firm although this is an unreliable sign. Skin pallor may be apparent as well as paresthesias (eg, burning sensation, numbness, tingling) and paralysis of the involved muscles. A very late sign of compartment syndrome is pulselessness.

8. What should your treatment of compartment syndrome include?

There is no specific treatment for compartment syndrome at the AEMT level, other than supportive care. The definitive treatment for compartment syndrome is surgical intervention, so rapid transport to the correct facility is important.

Narrative

EMS assigned to stand by at Running Eagle rodeo ground for high school rodeo. Called to arena for male bucked off a bull. Patient presents AO×4, ABCs intact, obvious deformity to left leg and unstable pelvis. Requested air medical transport; not available. 15 L/min via nonrebreathing applied. Prior to movement, cervical collar and spinal immobilization applied, along with pelvic splint with some relief from pain. Placed patient on stretcher, secured, transport emergent. En route, established bilateral IVs with normal saline—one IV running wide open, one IV TKO. Approximately 35 minutes into transport, patient has signs and symptoms consistent with compartment syndrome—severe pain in his femoral area and tingling in left foot. Assessment reveals firmness in femur and decreased sensation in left foot. Contacted receiving physician, who suspects compartment syndrome and advises rapid transport. Preparation made for rapid removal of patient on arrival at ED. On arrival, report given to receiving physician and ED staff without incident.

End of report

Prep Kit

Ready for Review

- Skeletal or voluntary muscle attaches to bone and forms the major muscle mass of the body. This muscle contains arteries, veins, and nerves.
- There are approximately 206 bones of the skeleton. When these living tissues are fractured, they can produce bleeding and severe pain.
- A joint is a junction where two bones come into contact. Joints are stabilized in key areas by ligaments.
- Tendons connect skeletal muscle to bone. Ligaments connect bone to bone and help maintain the stability of joints and determine the degree of joint motion. Cartilage is a flexible connective tissue that forms a smooth surface over bone ends where they articulate.
- Age-associated changes in the musculoskeletal system include decreased bone density, degeneration of joints, and disk herniation. People with osteoporosis have a higher risk of fracture.
- When a person has a musculoskeletal injury, many structures may be damaged, including muscles, bones, tendons, ligaments, cartilage, and vessels.
- A fracture is a broken bone; a dislocation is a disruption of a joint; a sprain is a stretching injury to the ligaments around a joint; and a strain is stretching of a muscle.
- A pathologic fracture, or nontraumatic fracture, occurs from a force that would usually not harm a healthy bone; however, due to a medical condition, the bone has become abnormally weak and more vulnerable to damage.
- Depending on the amount of kinetic energy absorbed by the tissues, the zone of injury may extend beyond the point of contact. Always maintain a high index of suspicion for associated fractures and other injuries.
- Fractures are classified as open or closed, and displaced or nondisplaced. Open and closed fractures are splinted in the same manner, but remember to control bleeding and apply a sterile dressing to the open extremity injury before splinting. Open fractures have a higher risk of infection.
- Other specific types of fractures include greenstick, comminuted, epiphyseal, oblique, transverse, spiral, and incomplete.
- The most common life-threatening musculoskeletal injuries are multiple fractures, open fractures with arterial bleeding, pelvic fractures, bilateral femur fractures, and limb amputations.
- Fractures and dislocations are often difficult to diagnose without a radiographic examination. You will treat these injuries similarly. Stabilize the injury with a splint, and transport the patient.
- Signs of a fracture and dislocation include pain, deformity, point tenderness, guarding, loss of use, swelling, bruising, crepitus, and false motion. Signs specific to fractures include shortening and exposed bone ends.
- Signs of a sprain (ligament injury) include swelling, ecchymosis, and instability of the joint.
- Signs of a strain (pulled muscle) include pain, but there is often no deformity and only minor swelling at the site of injury.
- Compare the unaffected extremity with the injured extremity for differences whenever possible.
- Interventions for patients with musculoskeletal injuries include addressing the ABCs; splinting; securing critical patients to a long backboard; providing prompt transport, possibly to a

trauma center; and establishing IV access with possible administration of IV fluids.

- For each limb, your neurovascular examination should include assessment of pulse and motor and sensory function. Repeat this exam every 5 to 10 minutes.
- The principles of splinting include the following: if you suspect a fracture of the shaft of any bone, ensure the splint stabilizes the joints above and below the fracture; with injuries in and around a joint, ensure the splint immobilizes the bones above and below the injured joint; and where fracture of a long bone shaft has resulted in severe deformity, use constant, gentle, manual traction (pull) to align the limb so it can be splinted, unless this is too painful.
- There are three types of splints: traction splints, rigid splints, and formable splints.
- Neurovascular injury is a potential complication of musculoskeletal injury. Treatment is to assess and reassess pulses, control bleeding, and maintain adequate intravascular volume by administering IV fluid.
- Compartment syndrome is a complication of a musculoskeletal injury that occurs when bleeding or swelling leads to increased pressure within the space a muscle occupies. This pressure can impair circulation and cause pain, sensory changes, and muscle death.

Compartment syndrome can occur in both open and closed fractures. Immediate transport is crucial.

- Crush syndrome may occur when an entrapped limb has been compressed and is then freed, causing the release of harmful products (rhabdomyolysis). Before releasing the compressing force, administer supplemental oxygen to the patient as needed and consider contacting medical direction regarding administering a bolus of crystalloid solution.
- A sling and swathe is used commonly to treat shoulder dislocations and to secure injured upper extremities to the body. Lower extremities can be secured to the unaffected limb or to a long backboard.
- Pelvic binders can be used to splint the pelvis. Another option may be to use a PASG, depending on local protocols.
- Amputations may be partial or complete. Amputated parts may often be reattached by surgeons. Correct prehospital care of the amputated part is vital to successful reattachment. Never sever a partial amputation, and always control bleeding.
- Sprains and strains should be treated with rest, ice, compression, elevation, and pain management. Also, protect the limb from bearing weight.

Vital Vocabulary

abduction Movement of a limb *away* from the midline of the body.

adduction Movement of a limb *toward* the midline of the body.

amputation An injury in which part of the body is completely severed; complete avulsion.

angulation In a fracture, when each end of the fracture is not aligned in a straight line and an angle has formed between them.

appendicular skeleton The portion of the skeletal system that comprises the arms, legs, pelvis, and shoulder girdle.

articulation A movable joint formed where bones or cartilage come in contact with each other.

axial skeleton The part of the skeleton comprising the skull, spinal column, and rib cage.

buddy splinting Securing an injured finger or toe to an adjacent uninjured one to allow the intact digit to act as a splint.

cartilage The support structure of the skeletal system that provides cushioning between bones; it also forms the nasal septum and portions of the outer ear.

closed fracture A fracture in which the skin is not broken.

compartment syndrome An elevation of pressure within the fascial compartment, characterized by extreme pain, decreased pain sensation, pain on stretching of affected muscles, and decreased power; most frequently seen in fractures below the elbow or knee in children.

crepitus A grating or grinding sensation caused by fractured bone ends or joints rubbing together; also, air bubbles under the skin that produce a crackling sound or crinkly feeling.

crush syndrome Significant metabolic derangement that develops when crushed extremities or body parts remain trapped for prolonged periods; it can lead to renal failure and death.

deep vein thrombosis (DVT) The formation of a blood clot within the larger veins of an extremity, typically following a period of prolonged immobilization.

devascularization The loss of perfusion to a part of the body.

dislocation Disruption of a joint in which ligaments are damaged and the bone ends are completely displaced.

displaced fracture A fracture in which bone fragments are separated from one another and are not in anatomic alignment.

ecchymosis Bruising or discoloration associated with bleeding within or under the skin.

fascia The fiberlike connective tissue that covers arteries, veins, tendons, and ligaments.

fracture A break in the continuity of a bone.

hematopoiesis The process of generating blood cells.

hematuria The presence of blood in the urine.

indirect injury An injury that occurs when force is applied to one region of the body but causes an injury in another area.

joint The point at which two or more bones articulate, or come together.

lactic acid A metabolic end product of the breakdown of glucose that accumulates when metabolism proceeds in the absence of oxygen.

lateral compression A force that is directed from the side toward the midline of the body.

ligament A band of fibrous tissue that connects bones to bones; supports and strengthens a joint.

neurovascular compromise The loss of the nerve supply, blood supply, or both to a region of the body, typically distal to a site of injury; characterized by alterations in sensation, including numbness and tingling, or by a loss or decrease of motor function; vascular compromise is indicated by weak or absent pulses, poor skin color, and cool skin.

nondisplaced fracture A simple crack in the bone that has not caused the bone to move from its normal anatomic position; also called a hairline fracture.

open book pelvic fracture A life-threatening fracture of the pelvis caused by a force that displaces one or both sides of the pelvis laterally and posteriorly.

open fracture Any break in a bone in which the overlying skin has been damaged.

osteoporosis A generalized bone disease, commonly associated with postmenopausal women but occurring in either sex, in which there is a reduction in the amount of bone mass, resulting in increased susceptibility to fractures after minimal trauma.

paresthesias Abnormal sensations such as burning, numbness, or tingling.

pathologic fracture A fracture that occurs in an area of abnormally weakened bone.

pelvic binders Devices used to splint the bony pelvis to reduce hemorrhage from bone ends, venous disruption, and pain.

physis The growth plate in long bones.

plantar flexion Bending of the foot toward the ground.

point tenderness Tenderness that is sharply localized at the site of the injury, found by gently palpating along the bone with the tip of one finger.

pulmonary embolism A blood clot that breaks off from a large vein and travels to the blood vessels of the lung, causing obstruction of blood flow.

reduction Repositioning of a bone to near its normal position after a fracture or dislocation.

retroperitoneal space The space between the abdominal cavity and the posterior abdominal wall, which contains the kidneys, certain large vessels, and parts of the gastrointestinal tract.

rhabdomyolysis The destruction of muscle tissue leading to a release of potassium and myoglobin.

sciatic nerve The major nerve to the lower extremity; it controls much of the muscle function in the leg and sensation in the entire leg and foot.

six Ps of musculoskeletal assessment Pain, Paralysis, Paresthesias, Pulselessness, Pallor, and Pressure.

sling A bandage or material that helps to support the weight of an injured upper extremity.

splint A flexible or rigid appliance used to protect and maintain the position of an injured extremity.

sprain A joint injury involving damage to supporting ligaments (stretching or tearing) and partial or temporary dislocation of bone ends.

straddle fracture A fracture of the pelvis that results from landing on the perineal region.

strain Stretching or tearing of a muscle or tendon; also called a muscle pull.

subluxation A partial or incomplete dislocation of a joint.

swathe A bandage that passes around the chest to secure an injured arm to the chest.

tendons Tough, ropelike cords of fibrous tissue that attach skeletal muscle to bone.

tourniquet A bandage or device applied to an extremity to control bleeding, used when a wound continues to bleed despite the use of direct pressure; works by compressing or constricting blood flow.

traction The act of exerting a pulling force on a body.

vertical shear The type of pelvic fracture that occurs when a massive force displaces the pelvis superiorly.

zone of injury The entire affected area in a bone or joint injury, which may include the surrounding soft tissues, especially to the adjacent nerves and blood vessels.

Chapter 34

Environmental Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Environmental Emergencies

Recognition and management of

- Submersion incidents (pp 1629–1631, 1634–1635)
- Temperature-related illness (pp 1599–1602)

Pathophysiology, assessment, and management of

- Near drowning (pp 1621–1622)
- Temperature-related illness (pp 1614–1616)
- Bites and envenomations (pp 1639–1648)
- Dysbarism
 - High-altitude (pp 1635–1636)
 - Diving injuries (pp 1622–1627)
- Electrical injury (pp 1636–1638, and see Chapter 28, *Soft-Tissue Injuries*)
- Radiation exposure (see Chapter 28, *Soft-Tissue Injuries*)

KNOWLEDGE OBJECTIVES

1. Describe four factors that affect how a person deals with exposure to a cold or hot environment and how each one relates to emergency medical care. (pp 1599–1600)
2. Explain the five different ways a body can lose heat and ways the rate and amount of heat loss or gain can be modified in an emergency situation. (pp 1600–1602)
3. Define and discuss hypothermia, including the signs and symptoms of its four different stages and the risk factors for developing it. (pp 1602–1605)
4. Explain local cold injuries and their underlying causes. (pp 1605–1606, 1608)
5. Describe the process of providing emergency care to a patient who has sustained a cold injury, including assessment of the patient, and management of care. (pp 1606–1613)
6. Explain the importance of following regional and state protocols when rewarming a patient who is experiencing moderate or severe hypothermia. (pp 1604–1605)
7. Describe the three forms of illness that are caused by heat exposure, including their signs and symptoms, and give examples of persons who are at the greatest risk of developing one of them. (pp 1613–1616)

8. Describe the process of providing emergency care to a patient who has sustained a heat injury, including assessment of the patient, and management of care. (pp 1616–1620)
9. Define *drowning* and discuss its incidence, risk factors, and prevention. (pp 1621–1622)
10. Describe three physical laws that affect pressure in the context of diving and diving-related conditions. (pp 1622–1623)
11. Describe the three different types of diving emergencies, how they may occur, and their signs and symptoms. (pp 1622–1628)
12. List the basic rules of performing a water rescue, and discuss why rescue personnel should have a prearranged water rescue plan based on the environment in which they work. (pp 1628–1629)
13. List four conditions that may result in a spinal injury following a submersion incident and the steps for stabilizing a patient with a suspected spinal injury in the water. (pp 1629–1631)
14. Discuss recovery techniques you may need to follow when managing a patient who has been involved in a submersion incident. (pp 1629–1631, 1634–1635)
15. Describe the process of providing emergency care to a patient who has been involved in a drowning or diving emergency, including assessment of the patient, and management of care. (pp 1631–1635)
16. Discuss the types of dysbarism injuries that may be caused by high altitudes, including their signs and symptoms and emergency medical treatment in the field. (pp 1635–1636)
17. Discuss lightning injuries, including their incidence, risk factors, assessment, and emergency medical treatment. (pp 1636–1639)
18. Identify the species of spiders found in the United States that may cause life-threatening injuries, and then describe the process of providing emergency care to patients who have been bitten by each type. (pp 1639–1641)
19. Discuss the emergency medical care of patients who have been stung by Hymenoptera, including steps you should follow if a patient develops a severe reaction to the sting or bite. (p 1641)
20. Identify the species of snakes found in the United States that are venomous, and then describe the process of providing emergency care to patients who have been bitten by each type and are showing signs of envenomation. (pp 1641–1646)
21. Discuss the emergency medical care of patients who have been stung by scorpions or bitten by ticks, including steps you should follow if a patient develops a severe reaction to the sting or bite. (pp 1646–1647)
22. Discuss the emergency medical care of patients who have been stung by a coelenterate or other marine animal. (pp 1647–1648)

SKILLS OBJECTIVES

1. Demonstrate the emergency medical treatment of local cold injuries in the field. (pp 1612–1613)
2. Demonstrate using a warm-water bath to rewarm the limb of a patient who has sustained a local cold injury. (p 1611)
3. Demonstrate how to treat a patient with heat cramps. (p 1618)
4. Demonstrate how to treat a patient with heat exhaustion. (p 1619, Skill Drill 34-1)
5. Demonstrate how to treat a patient with heatstroke. (p 1620)
6. Demonstrate how to stabilize a patient with a suspected spinal injury in the water. (pp 1630–1631, Skill Drill 34-2)
7. Demonstrate how to care for a patient who is suspected of having an air embolism or decompression sickness following a drowning or diving emergency. (p 1628)
8. Demonstrate how to care for a patient who has been bitten by a pit viper and is showing signs of envenomation. (pp 1644–1645)
9. Demonstrate how to care for a patient who has been bitten by a coral snake and is showing signs of envenomation. (pp 1644–1645)
10. Demonstrate how to care for a patient who has sustained a coelenterate envenomation. (pp 1647–1648)

Introduction

An **environmental emergency** is a medical condition caused or exacerbated by the weather, terrain, or atmospheric pressure at high altitude or underwater. Environmental factors such as temperature and atmospheric pressure can overwhelm the body's mechanisms for regulating temperature, including sweating and the radiation of body heat into the atmosphere.

A variety of medical emergencies can result, particularly in children, older people, people with chronic illnesses, and young adults who overexert themselves. These can result in mental status changes, functional changes, and, possibly, death. The environmental effect on morbidity and mortality increases with stressors that induce or exacerbate other medical or traumatic conditions.

In addition, a range of medical emergencies also arise from water recreation, which can sometimes be complicated by cold temperatures. These emergencies include localized injuries and systemic illnesses.

As an advanced emergency medical technician (AEMT), you can save lives by recognizing and responding properly to these emergencies, most of which require prompt treatment in the hospital.

In this chapter, you will learn how the body regulates **core temperature**, and the ways in which body heat is lost to the environment. The various forms of heat-, cold-, and water-related emergencies are described, including how to diagnose and treat **hypothermia**, **frostbite**, and **hyperthermia**. You will also learn about pressure-related emergencies, or **dysbarism injuries**, caused by diving and high-altitude climbing; injuries caused by lightning; and envenomation, caused by bites and stings.

Factors Affecting Exposure

The body works to ensure balance between heat production and heat excretion (**thermoregulation**). A rise in core body temperature elicits responses that increase heat loss and shut off normal heat production pathways (called **thermogenesis**); a decrease in core body temperature prompts heat production and conservation and turns off normal heat-liberating pathways (called **thermolysis**) (**FIGURE 34-1**).

There are four factors that affect how a person deals with a cold or hot environment. These can be used as prevention strategies for those who work or play in extreme environmental temperatures. They

FIGURE 34-1 Similar to a thermostat, the hypothalamus notes a rise or fall in core body temperature and elicits responses to regulate it.

YOU are the Provider

Part 1

Your ambulance is dispatched to an unresponsive man who is outside a local fast food establishment. As you proceed to your ambulance, you tell your partner that this will probably be hypothermia induced by the -20°F (-28°C) temperatures and 12 inches (30 cm) of snow on the ground. As you arrive on scene, you are greeted by law enforcement officers who state that the patient is homeless and they believe he was trying to sleep in front of the door in an effort to keep warm.

1. What are four factors that affect exposure?
2. What are the five methods of heat loss?

can also be useful during the assessment of your patient to determine how prepared the patient was for a cold or hot environment. A hiker prepared for a warm summer hike in the foothills will present and respond to treatment differently from a traveler stranded in a hot vehicle because the radiator boiled over. Factors affecting exposure include:

1. **Physical condition.** Patients who are already ill or in poor physical condition will not be able to tolerate extreme temperatures as well as those whose cardiovascular, metabolic, and nervous systems are all functioning well. For example, an athlete in peak physical condition performs better and is less likely to experience injury or illness than a person who is not in peak physical condition. Exertion also plays a role. Increasing your activity will generate more heat, which is beneficial in the cold but potentially problematic when it is hot.
2. **Age.** Children and older adults are more likely to experience temperature-related illness. Infants have poor thermoregulation at birth and do not have the ability to shiver and generate heat when needed until about 12 to 18 months. Their surface area-to-body mass ratio is larger, contributing to their more rapid heat loss and heat gain. When you get cold, you put on a sweater; a small child may not think to do this or may have difficulty finding and putting one on. On the other end of the spectrum, older adults lose subcutaneous tissue as they age, reducing the amount of insulation they have and their ability to tolerate temperature extremes. This is why older people often wear extra layers of clothing. Poor circulation also contributes to increased risk of frostbite. Medications can also affect an older person's body thermostat, putting the person at increased risk for temperature-related emergencies. Finally, older patients are at high risk for falls, and lying immobile on a hot or cold surface can rapidly result in overexposure.
3. **Nutrition and hydration.** The body needs calories for its metabolism to function. Staying well hydrated provides water as a catalyst for much of this metabolism. A decrease in calorie intake or water intake increases susceptibility to heat or cold illness or injury. Calories provide fuel to burn, creating heat during the cold, and water provides sweat for **evaporation** and removing heat. Alcohol use may increase

fluid loss and place the patient at greater risk for temperature-related emergencies.

4. **Environmental conditions.** Conditions such as air temperature, humidity levels, and wind can complicate or improve environmental situations. A cool breeze helps when it is hot outside, but a cold wind when it is cold outside can be uncomfortable. Extremes in temperature and humidity are not needed to produce hot or cold injuries. Many hypothermia cases occur at temperatures between 30°F (−1°C) and 50°F (10°C). Most **heatstroke** cases occur when the temperature is 80°F (26.7°C) and the humidity is 80%; however, heat injury can also occur at moderate temperatures when there is a combination of extreme exertion and inadequate hydration.¹ Be sure to examine the environmental temperature of your patient. Older patients may turn the heat down in the winter or neglect to use air conditioning in the summer because of cost concerns. Some people may not open windows in a heat wave for fear of burglars. When evaluating your patient's condition, consider the environment and whether your patient is prepared for that situation. It may help in your treatment decisions and give you an idea about how the patient will respond to your care.

Cold Exposure

Normal body temperature must be maintained within a narrow range for the body's chemistry to work efficiently. Homeostasis, or a constant internal balance, must be maintained. If the body, or any part of it, is exposed to a cold environment, these mechanisms may be overwhelmed. Cold exposure may cause injury to individual parts of the body, such as the feet, hands, ears, or nose, or to the body as a whole. When the entire core body temperature falls because of inadequate internal heat production (thermogenesis), excess cold stress, or a combination of both, the condition is called *hypothermia*.

Because heat always travels from a warmer place to a cooler place, the body will tend to lose heat to the environment. Through thermolysis, or methods of heat loss, the body can lose heat in the following five ways:

- **Conduction** is the direct transfer of heat from a part of the body to a colder object or substance by direct contact, such as when a warm

FIGURE 34-2 Chart used to determine wind-chill factor.

Courtesy of the National Weather Service/NOAA.

hand touches cold metal or ice, is immersed in cold water, or lies on a cold surface such as pavement. Heat passes directly from the body to the colder object. Heat can also be gained if the object or substance being touched is warm. This is why people with chronic medical problems are advised to limit time in hot tubs.

- **Convection** occurs when heat is transferred to circulating air, such as when cool air moves across the body surface. A person standing outside in windy winter weather, wearing only lightweight clothing, is losing heat to the environment mostly by convection. The **wind-chill factor** measures the chilling effect of a given temperature at a given wind speed. For example, the chilling effect of a 30°F (−1.1°C) **ambient temperature** (the temperature of the surrounding environment) with a 35-mph wind is −4°F (−20.0°C) (**FIGURE 34-2**). A person can gain heat if the air moving across the person's body is hotter than the temperature of the environment, such as in deserts or industrial settings like foundries, but it is more common to see rapid heat gain in spas and hot tubs where the water temperature may be well above body temperature (**FIGURE 34-3**).
- Evaporation is the conversion of a liquid to a gas, a process that requires energy, or heat.

Evaporation is the natural mechanism by which sweating cools the body. This is why swimmers coming out of the water feel a sensation of cold as the water evaporates from their skin. People who exercise vigorously in a cool environment may sweat and feel warm at first, but later, as their sweat evaporates, they can become cold.

- **Radiation** is the loss of body heat directly to colder objects in the environment by radiant energy. Radiant energy is a type of invisible light that transfers heat. Because heat always travels from a warm object to a cooler one, a person standing in a cold room will lose heat by radiation. Heat can also be gained by radiation: for example, when a person stands by a fire.
- Respiration causes body heat to be lost, as warm air in the lungs is exhaled into the atmosphere and cooler air is inhaled. In warm climates, the air temperature can be well above body temperature, causing an individual to gain heat with each breath.

The rate and amount of heat loss or gain by the body can be modified in three ways:

1. **Increase or decrease heat production.** One way for the body to increase its heat production

FIGURE 34-3 Chart used to determine heat index.

Courtesy of National Oceanic and Atmospheric Administration.

is to increase the rate of metabolism of its cells; the body can accomplish this through shivering. In addition, people often have a natural urge to move around when they are cold. People who are hot tend to reduce their level of activity, thus reducing heat production.

2. **Move to an area where heat loss is decreased or increased.** The most obvious ways to decrease heat loss from radiation and convection are to move out of a cold environment and seek shelter from the wind. The same holds true for a patient who is too hot. Simply moving the patient into the shade can reduce the ambient temperature (the temperature of the surrounding environment) by 10° or more. If you cannot move the patient, create shade and increase air movement by fanning the patient.
3. **Wear the appropriate clothing for the environment.** To avoid heat loss in cold environments, wear layers of clothing that provide good insulation, such as wool, down, and synthetic fabrics that have small pockets of trapped air. Protective clothing traps perspiration and prevents evaporation, which prevents cooling. Keep the head, hands, and feet covered, and remove wet clothing if possible.

Sweating without evaporation will not result in cooling. To encourage heat loss, wear lightweight, loose-fitting clothing, particularly around the head and neck.

Pathophysiology

Hypothermia

Hypothermia literally means “low temperature.” It occurs when the core temperature of the body (the temperature of the heart, lungs, and vital organs) falls below 95°F (35°C). The body can usually tolerate a decrease in core temperature of a few degrees. However, below this critical point, the body cannot regulate its temperature and generate body heat. Progressive loss of body heat then begins.

To protect itself against heat loss, the body normally constricts blood vessels in the skin; this results in the characteristic pale appearance of the hypothermic patient. As a secondary compensatory mechanism against heat loss, the body attempts to create additional heat by shivering, which is the active moving of many muscles to generate heat. Many body functions begin to slow down as cold exposure continues and these mechanisms are overwhelmed. Eventually, the functioning of key organs such as

the heart and brain begins to slow. Untreated, this can result in coma and eventually death.

Hypothermia can develop either quickly, as when someone is immersed in cold water, or gradually, as when a person is exposed to the cold environment for several hours or more. The temperature does not have to be below freezing (less than 32°F [0°C]) for hypothermia to occur. In winter, homeless people and those whose homes lack heating may develop hypothermia at higher temperatures. Even during summer, swimmers who remain in the water for extended periods are at risk of hypothermia. Like all heat- and cold-related injuries, hypothermia is more common among geriatric, pediatric, and ill populations who are less able to adjust to temperature extremes. Also, infants and children have a relatively large body surface area in relation to mass and have less body fat than do adults. Therefore, an infant or child who is not clothed appropriately can develop hypothermia.

Patients with injuries or illness, such as burns, shock, head injury, stroke, generalized infection, injuries to the spinal cord, malnutrition, hypothyroidism, diabetes, and hypoglycemia, are more susceptible to hypothermia, as are patients who have taken certain drugs or poisons.

Alcohol is a common contributor to hypothermia.² It predisposes the patient to hypothermia by impairing shivering (decreased thermogenesis) and

by promoting cutaneous vasodilation (increased thermolysis), which hinders the body's attempts to create an insulating shell around its warm core. Liver disease, which results in inadequate glycogen stores, and the subnormal nutritional status of most people with alcoholism further impair metabolic heat generation. Finally, alcohol impairs judgment, which often results in inappropriate behavior in cold conditions. Impaired thermoregulation can also occur with therapeutic use or overdoses of sedative medications, tricyclic antidepressants, and phenothiazines, primarily by interfering with central nervous system-mediated vasoconstriction.

Special Populations

Because of their small muscle mass, children may not be able to shiver as effectively as adults, and infants do not shiver at all.

Signs and Symptoms

Signs and symptoms of hypothermia increase in severity as the core temperature falls. Hypothermia generally progresses through four stages, as shown in **TABLE 34-1**. Although there is no clear distinction among the stages, the different signs and symptoms

TABLE 34-1 Characteristics of Systemic Hypothermia

Extent of hypothermia	Mild: 95°F to 90°F (35°C to 32°C)	Moderate: 90°F to 82°F (32°C to 28°C)		Severe: <82°F (28°C)
Core temperature	95°F to 93°F (35°C to 33.9°C)	92°F to 89°F (33.3°C to 31.7°C)	88°F to 80°F (31.1°C to 26.7°C)	<80°F (<26.7°C)
Signs and symptoms	Shivering, foot stamping	Loss of coordination, muscle stiffness	Coma	Apparent death
Cardiorespiratory response	Constricted blood vessels, rapid breathing	Slowing respirations, slow pulse	Weak pulse, dysrhythmias, very slow respirations	Cardiac arrest
Level of consciousness	Withdrawn	Confused, lethargic, sleepy	Unresponsive	Unresponsive

of each will help you estimate the severity of the hypothermia. When you assess a patient in the field, you should be able to distinguish between mild and severe hypothermia.

Words of Wisdom

The National Institutes of Health has initiated a public awareness campaign informing the public to watch for “umbles”: fumbles (coordination and fine motor control problems), stumbles, mumbles (speech difficulty), and crumbles (incoherence, hemodynamic collapse). These behaviors are good indicators of how the cold affects the cerebral and cognitive functioning of patients in the early stages (mild) of hypothermia. Older people may simply have a flatter affect, be slightly more confused, or develop symptoms suggestive of a possible stroke, including dysarthria and ataxia.

It is important to assess the temperature of the patient’s skin close to the trunk, or core, of the body. Extremities may be cold as a result of exposure, yet the patient may be hemodynamically stable. To assess the patient’s core body temperature, pull your glove back and place the back of your hand on the patient’s skin at the abdomen (**FIGURE 34-4**). If the skin feels cool, the patient is likely experiencing a generalized cold emergency. Rectal temperature is considered the most accurate for assessment of hypothermia, but rectal thermometers are not typically available in ambulance equipment. Oral and

FIGURE 34-4 To assess a patient’s core body temperature, pull back your glove and place the back of your hand on the patient’s skin at the abdomen.

© Jones & Bartlett Learning.

tympanic thermometers may be markedly off when measuring core body temperature.

If you work in a cold environment, and/or depending on local protocols, you may carry a hypothermia thermometer, which registers lower core temperatures. It must be inserted into the rectum for an accurate reading. Regular thermometers will not register the temperature of a patient who has substantial hypothermia.

Mild hypothermia occurs when the core temperature is between 95°F and 93°F (35°C and 33.9°C). The patient is usually alert (may be withdrawn, anxious, or restless) and shivering in an attempt to generate more heat through muscular activity. In a further attempt to generate body heat, the patient may jump up and down and stamp the feet. Pulse rate and respirations are usually rapid. The skin in light-skinned people can be red but may eventually appear pale and then cyanotic. When in a cold environment, they may have blue lips or fingertips because of the body’s constriction of blood vessels at the skin to retain heat. Paleness, or a decrease in blood flow, is more difficult to detect in dark-skinned people. Examine the mucous membranes inside the lower eyelids and the patient’s gums; in children, check capillary refill.

Moderate hypothermia exists when the core temperature is 92°F to 89°F (33.3°C to 31.7°C). As the body compensates, the patient may present with signs and symptoms of a cold emergency while maintaining a normal core body temperature. The temperature is actually being maintained by thermogenesis. As energy stores of glycogen in the liver and muscles are exhausted, the core body temperature begins to drop. Shivering stops, and muscular activity decreases. At first, small, fine muscle activity such as coordinated finger motion ceases. Eventually, as the temperature decreases further, all muscle activity stops.

As the core temperature drops toward 85°F (29.4°C), patients become lethargic, usually losing the ability to continue to fight the cold. The level of consciousness decreases, and patients may try to remove their own clothes as a result of altered mental status. Poor coordination and memory loss follow, along with reduced or complete loss of sensation to touch, mood changes, and impaired judgment. These patients become less communicative, experience joint or muscle stiffness, and have trouble speaking. They begin to appear stiff or rigid.

If the core temperature continues to fall to 80°F (26.7°C), vital signs slow; the pulse becomes weaker, and respirations decrease in rate and depth or become absent altogether. Cardiac dysrhythmias may occur as a direct effect of cold as cardiac tissue becomes more irritable, or as the blood pressure decreases.

At a core temperature of less than 80°F (26.7°C), all cardiorespiratory activity may cease, pupillary reaction is slow, and the patient may appear dead.

*Never assume that a cold, pulseless patient is dead. Patients are not dead until they are **warm and dead**.* Patients may survive even severe prolonged hypothermia if proper emergency care is provided.

Street Smarts

The stress of the cold environment, a remote terrain, a feeling of impending doom, and impaired judgment may result in suicidal tendencies in some patients with hypothermia. It is important to protect patients from harming themselves while considering your own safety at all times.

Local Cold Injuries

Most injuries from cold are localized to exposed parts of the body. The extremities, particularly the feet and hands, and the ears, nose, and face are especially vulnerable to cold injury (**FIGURE 34-5**). When exposed parts of the body become very cold but not frozen, injuries such as **frostnip**, chilblains, or **immersion foot** (also called trench foot) can

result. When the parts become frozen, the injury is called frostbite. Frostnip is reversible on rewarming (there is no blister formation, and color returns to normal), but frostbite is not.

In systemic hypothermia, blood is shunted away from the extremities to maintain the core temperature. This shunting of blood increases the risk of local cold injury to the extremities, ears, nose, and face. Thus, the patient with systemic hypothermia should also be assessed for frostbite or other local cold injury. The reverse is also true. Remember that both local and systemic cold exposure injuries can occur in the same patient.

Frostnip and Immersion Foot

After prolonged exposure to the cold, the skin may begin to freeze while the deeper tissues are unaffected. This condition, which often affects the ears, nose, and fingers, is called frostnip. Because frostnip is usually not painful, the patient is often unaware that a cold injury has occurred. Immersion foot occurs after prolonged exposure to cold water. It is particularly common in hikers or hunters who stand for a long time in a river or lake. In both frostnip and immersion foot, the skin is pale (blanched) and cold to the touch; normal color does not return after palpation of the skin. In some cases, the skin of the foot will be wrinkled, but it can also remain soft. The patient reports loss of feeling and sensation in the affected area.

Frostbite

Frostbite is the most serious local cold injury because the tissues are actually frozen. Freezing

A

B

C

FIGURE 34-5 The tip of the nose (A), the extremities (B), and the ears (C) are particularly susceptible to frostbite.

FIGURE 34-6 Gangrene, or permanent cell death, can occur when tissue is frozen and chemical changes occur in the cells.

Courtesy of Dr. Jack Poland/CDC.

permanently damages cells via one of two mechanisms: direct cellular damage or progressive dermal ischemia.^{3,4} The presence of ice crystals within the cells may cause physical damage. The change in the water content in the cells may also cause changes in the concentration of critical electrolytes, producing permanent changes in the chemistry of the cell. When the ice thaws, further chemical changes occur in the cell, causing permanent damage or cell death, called gangrene (**FIGURE 34-6**). If gangrene occurs, the dead tissue must be surgically removed, sometimes by amputation. Following less-severe damage, the exposed part will become inflamed, tender to the touch, and unable to tolerate further exposure to cold.

Frostbite can be identified by the hard, waxy feel of the affected tissues (**FIGURE 34-7**). The injured part feels firm to frozen as you gently touch it. If the frostbite is only skin deep, it will feel leathery or thick instead of hard. Blisters and swelling may be present. In people with a deep injury that has thawed or partially thawed, the skin may appear mottled and cyanotic.

As with a burn, the depth of skin damage will vary. With superficial frostbite, only the skin is frozen; with deep frostbite, the deeper tissues are frozen as well. You may not be able to tell superficial from deep frostbite in the field. Even an experienced surgeon in a hospital setting may not be able to tell until several days have passed.

FIGURE 34-7 Frostbitten skin is hard and usually waxy to the touch.

Assessment of Cold Injuries

Management of hypothermia in the field, regardless of the severity of the exposure, consists of stabilizing the ABCs (airway, breathing, and circulation) and preventing further heat loss. All patients who are injured are at risk for hypothermia. Keep this in mind when you are evaluating a patient with multiple injuries.

Scene Size-up

Typically, your scene assessment begins with information provided by dispatch and consideration of the environmental conditions. Air temperature, wind chill, and whether it is wet or dry are important aspects of scene size-up and will likely affect the patient.

Ensure that the scene is safe for you and other responders. Identify potential safety hazards, such as wet grass, mud, snow, or icy streets. Consider special hazards such as avalanches. Cold environments may present special problems both for you and your patient. Use appropriate standard precautions, including dressing appropriately for the weather, and consider the number of patients you may have. Summon additional help, such as a search-and-rescue team, as quickly as possible.

As you observe the scene, look for indicators of the mechanism of injury (MOI). This helps you develop an early index of suspicion for underlying

injuries in the patient who has sustained a significant MOI. For example, if you find a vehicle in a secluded ditch off the highway and the vehicle's roof and hood are covered with fresh snow, then you may assume that the patient was in a motor vehicle crash and has been exposed to the cold for a long period. Or the cause may be unrelated to trauma—for example, when a person becomes lost and is stranded overnight.

Primary Survey

In a cold emergency, your patients' chief complaint may be only that they are cold, or the cold may complicate an existing medical condition or injury. Perform a rapid full-body scan to determine whether a life threat exists, and if so, treat it. If the chief complaint is simply being cold, quickly assess the patient's core temperature by placing the back of your hand on the abdomen. Evaluate the patient's mental status quickly using the AVPU scale (Alert to person, place, and day; responsive to Verbal stimuli; responsive to Pain; Unresponsive). An altered mental status can indicate the intensity of the cold injury.

Your assessment should account for the physiologic changes that occur as a result of hypothermia. If you believe the patient is in cardiac arrest, proceed directly to the circulation ("C") step by providing high-quality chest compressions, and address airway and breathing ("A and B") afterward. If you cannot feel a radial pulse, gently palpate for a carotid pulse, and wait for up to 60 seconds before you decide that the patient is pulseless. Some physicians disagree about performing cardiopulmonary resuscitation (CPR) on a patient with hypothermia who appears to be pulseless. Such a patient actually may be in a kind of metabolic ice box, having achieved a metabolic balance that CPR may disrupt; therefore, some recommend that CPR may be delayed or suspended in severe hypothermia to allow for evacuation of the patient from the place where the person was found.⁵ Even a pulse rate of 1 or 2 beats/min indicates cardiac activity, and cardiac activity may spontaneously recover after the body core is warmed. However, CPR, when performed correctly, will increase blood flow to the critical parts of the body. For this reason, some authorities recommend starting CPR on a patient with hypothermia and

no pulse. The American Heart Association recommends that CPR be started if the patient has no detectable pulse or breathing.⁶ Again, for a patient with hypothermia, this may require a prolonged pulse check of up to 60 seconds.

Perfusion will be compromised based on the severity of the cold exposure. Your assessment of the patient's skin will not be helpful in determining shock. Assume that shock is present and treat it appropriately. Bleeding may be difficult to find because of the slow-moving circulation and thick clothing. If the scene size-up, MOI, or chief complaint suggests the potential for bleeding, look for it.

After immediate circulation concerns are addressed, ensure that the patient has an adequate airway and is breathing. If your patient's breathing is slow or shallow, ventilation with a bag-mask device may be necessary. Use warmed and humidified oxygen if it is available because it helps to warm the patient from the inside out.

Words of Wisdom

Oxygen may be warmed or cooled by taping hot packs or cold packs to the oxygen tubing, respectively. This will also work for intravenous (IV) fluids.

Even mild hypothermia can have serious consequences and complications, including cardiac dysrhythmias and blood clotting abnormalities. Therefore, all patients with hypothermia require immediate transport for evaluation and treatment. Assess the scene for the safest way to quickly move your patient from the cold environment. As you package your patient for transport, work quickly, safely, and gently. Gentle transportation is necessary. Rough handling of a patient with hypothermia may cause a cold, slow, weak heart to fibrillate and the patient to lose any pulse that may have existed; exertion can also trigger dysrhythmia in a cold heart. Transport the patient with the head level or slightly down. Always transport to the closest appropriate facility. Call in your radio report as soon as possible to allow time for the receiving facility to prepare for the patient. The availability of cardiac bypass rewarming capabilities would be preferable in considering the destination. If transportation is delayed, protect the patient from further heat loss.

Words of Wisdom

Handle patients with hypothermia *very gently*. Excessive movement increases the risk of inducing ventricular fibrillation.

History Taking

After the life threats have been managed during the primary survey, investigate the chief complaint. Obtain a medical history, and be alert for injury-specific signs and symptoms as well as any pertinent negatives.

Obtaining a patient's history in these situations may be difficult. If possible, determine the duration of the exposure, the temperature to which the body part was exposed, and the wind velocity during exposure, either from the patient or bystanders. These are important factors in determining the severity of a local cold injury. Exposures may be acute (such as a demented patient who wandered out into the cold) or chronic (as in the case of a homeless person living on the street). Your SAMPLE history (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) can provide important information affecting both your treatment in the field and the treatment your patient will receive in the hospital. Medications your patient has taken, alcoholic beverages your patient has consumed, and underlying medical conditions may influence the way cold affects the patient's metabolism. The patient's last oral intake and activity prior to the exposure will help to determine the severity of the cold injury.

You should also investigate several underlying factors:

- Exposure to wet conditions
- Inadequate insulation from cold or wind
- Restricted circulation from tight clothing or shoes or circulatory disease
- Fatigue
- Inadequate nutrition
- Alcohol or drug abuse
- Hypothermia
- Diabetes
- Cardiovascular disease
- Age

Secondary Assessment

Use the secondary assessment to uncover injuries that may have been missed during the primary survey. In some instances, such as a critically injured patient or a short transport time, you may not have time to conduct a secondary assessment.

Focus your physical examination on the severity of hypothermia, assessing the areas of the body directly affected by cold exposure, and the degree of damage. Is the whole body cold (hypothermia) or just isolated parts (frostbite)? These determinations will have important consequences for your treatment decisions. For example, shivering indicates a protective mechanism to produce more heat because the body is cold. When shivering stops and the patient remains in a cold environment, the cold injury is more severe.

Determine the degree and extent of cold injury, as well as any other injuries or conditions that may not have been initially detected. The numbing effect of cold, both on the brain and on the body, may impair your patient's ability to tell you about other injuries or illnesses. Therefore, a careful examination of your patient's entire body, with special attention to skin temperatures, textures, and **turgor**, will help you avoid missing important clues to your patient's condition.

Keep in mind that vital signs may be altered by the effects of hypothermia and can be an indicator of its severity. Respirations may be slow and shallow, resulting in low oxygen levels in the body. Low blood pressure and a slow pulse also indicate moderate to severe hypothermia. Carefully evaluate your patient for changes in mental status.

Determine a core body temperature using a hypothermia thermometer based on local protocol. Pulse oximetry will often be inaccurate because of the lack of perfusion in the extremities.

Reassessment

Repeat the primary survey. Reassess vital signs and the chief complaint. Review all treatments that have been performed. Has the patient's condition improved with the interventions? Identify and treat changes in the patient's condition. Keep a close eye on your patient's level of consciousness and vital signs. As the body rewarms, the sudden

redistribution of fluids and the release of built-up chemicals can have harmful effects, including cardiac dysrhythmias. Be vigilant and monitor your patient closely, even if the person's condition appears to be improving.

Communicate all information you have gathered to the receiving facility, which may be essential in evaluating and treating your patient in the hospital. Your documentation should always include the patient's physical status, the conditions at the scene, information gathered from bystanders, and any changes in the patient's mental status during treatment and transport.

Documentation and Communication

Recording specific results of your early assessment is particularly valuable when the patient has hypothermia. If there is a question regarding the initiation of CPR, note the anatomic location where you checked the pulse and for how long you checked it. Also note the initial body temperature and the anatomic location where it was taken. These points will be important to hospital staff and will help protect you if medicolegal issues ever arise.

Emergency Medical Care for Cold Emergencies

The following are general steps to take promptly to prevent further cold injury:

1. Remove wet clothing, and keep the patient dry.
2. Prevent conduction heat loss. Move the patient away from any wet or cold surfaces, such as a car frame.
3. Insulate all exposed body parts, especially the head, by wrapping them in a blanket or any other available dry, bulky material.
4. Prevent convection heat loss by erecting a wind barrier around the patient.
5. Remove the patient from the cold environment as promptly as possible.

FIGURE 34-8 illustrates recommendations for prehospital care of a hypothermic patient.

In most cases, you should move the patient from the cold environment to prevent further heat loss. To prevent further damage to the feet, do not allow the patient to walk. Provide for a warm environment by removing any wet or frozen clothing. Do not remove any clothing frozen to the patient's skin. Place dry blankets over and under the patient (**FIGURE 34-9**).

YOU are the Provider

Part 2

On approaching the patient, you find him to be responsive to deep, painful stimuli and breathing adequately at 14 breaths/min. You also note that his clothing is soaked from the snow, but he does not appear to be shivering. You ask the police officer if he can get your stretcher, and you ask your partner to turn up the heat all the way in the patient compartment while you perform a rapid assessment of the patient.

Recording Time: 1 Minute

Appearance	Poor
Level of consciousness	Responsive to deep painful stimuli
Airway	Patent
Breathing	Nonlabored
Circulation	Cold

3. Discuss ways to increase heat in the body.
4. What stage of hypothermia does this patient present in?

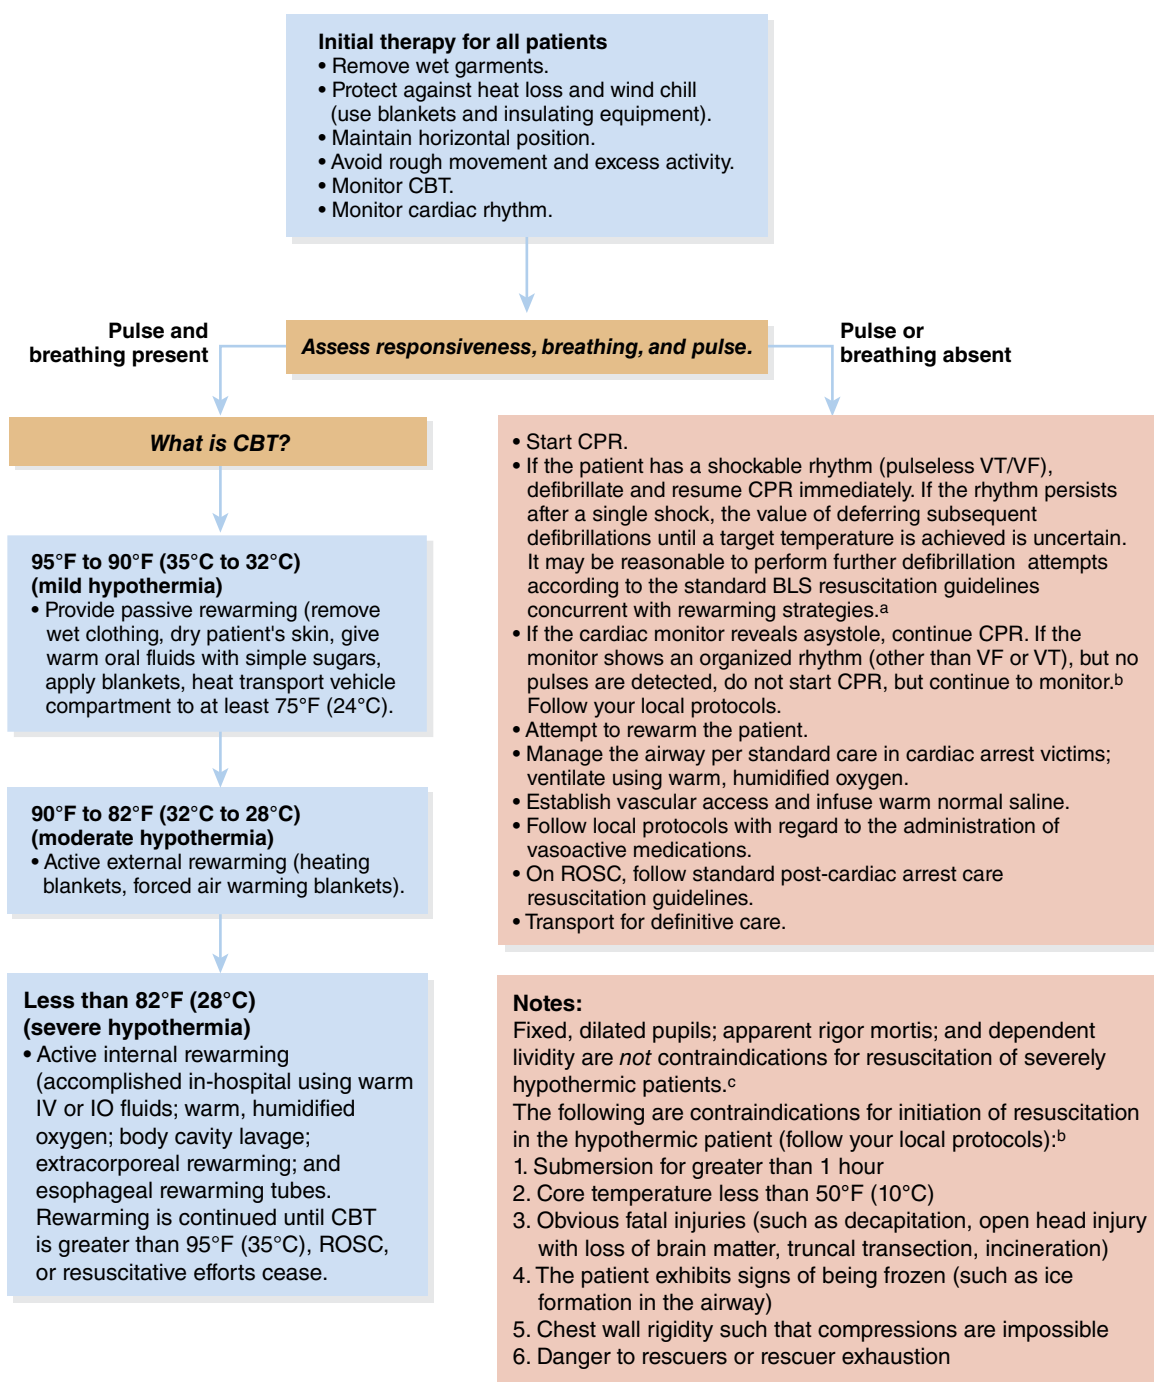

FIGURE 34-8 Prehospital hypothermia treatment algorithm. Note that some of the items in the algorithm, such as cardiac monitoring and administration of vasoactive medications, are performed at the paramedic level but not by AEMTs.

Abbreviations: BLS, basic life support; CBT, core body temperature; CPR, cardiopulmonary resuscitation; IO, intraosseous; IV, intravenous; ROSC, return of spontaneous circulation; VF, ventricular fibrillation; VT, ventricular tachycardia

FIGURE 34-9 Place dry blankets over and under the patient with hypothermia; give warm, humidified oxygen, if available; assess the pulse for up to 60 seconds before considering cardiopulmonary resuscitation.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

If available, give the patient warm, humidified oxygen. In a cold-related emergency, depending on your local and state protocols, your treatment may only include oxygen delivery (warmed and humidified if possible).

Obtain IV access, but follow local protocols for administering fluid to a patient with hypothermia. When possible, administer fluid that has been warmed so as not to further lower the core temperature. Also, check the blood glucose levels of any patient with an altered mental status or a history of diabetes.

Words of Wisdom

IV fluids may be warmed by placing them over a defroster or hanging them in front of a heater vent. If fluids are warmed, be sure to test the temperature (eg, run the fluid over your inner wrist like you would a baby's bottle) before infusing them into a patient.

Always handle the patient gently so that you do not cause any pain or further injury to the skin. Do not massage the extremities. Do not allow the patient to eat or to use any stimulants, such as coffee, tea, cola, or tobacco products.

If the patient is alert, shivering, responds appropriately, and the core body temperature is between 90°F and 95°F (32.2°C and 35°C), then the hypothermia is mild. Begin passive rewarming slowly,

which includes placing the patient in a warm environment, removing wet clothing, and applying heat packs or hot water bottles to the groin, axillary, and cervical regions. Turn the heat up high in the patient compartment of the ambulance. To avoid burns, do not place heat packs directly on the skin. If possible, you can give warm fluids by mouth, as allowed by local protocols, assuming that the patient is alert and can swallow without difficulty.

When the patient has moderate or severe hypothermia, active rewarming is best accomplished in the emergency department (ED) utilizing aggressive strategies to introduce heat to the body's core. Such therapies might include lavage with warm fluids and rewarming blood outside the body before reintroducing it (extracorporeal rewarming). In general, rewarming should occur rapidly; however, rewarming the patient too quickly may cause a fatal cardiac dysrhythmia or other substantial complications. Also, rewarming extremities too rapidly without rewarming the core can cause vasodilation, leading to return of cold blood from the limbs and causing further cooling of the core. For this reason, local protocols may dictate the appropriate type of rewarming strategy based on the patient's body temperature.

Words of Wisdom

Never place hot or cold packs directly against the patient's skin. Always wrap them in a towel or cloth to prevent burning or freezing the skin, respectively.

If you cannot get the patient out of the cold immediately, move the patient out of the wind and away from contact with any object that will conduct heat away from the body. Place a protective cover over and beneath the patient. Remember that most body heat is lost around the head and neck.

Regardless of the nature or severity of the cold injury, remember that even an unresponsive patient may be able to hear you.

Withholding and Cessation of Resuscitative Efforts

In the field, patients with obviously lethal traumatic injuries or those so solidly frozen as to block

the airway or chest compression efforts generally are dead. If submersion preceded the arrest, then successful resuscitation is unlikely, with the possible exception of people who have been submerged in icy waters. Trauma, alcohol overdose, and drug overdose could have resulted in hypothermia in the first place and can hamper resuscitation efforts. Try to factor these conditions into your treatment decisions, and seek input from medical control. For example, examination of a heroin user who was found outdoors and quickly recovers after naloxone administration requires you to obtain a full set of vital signs, including body temperature.

Some providers believe that patients who appear dead after prolonged exposure to cold temperatures are not dead until “warm and dead.” The effects of hypothermia may essentially protect the brain and organs if hypothermia develops quickly, a fact that is being used to successfully treat some cardiac arrest patients. Sometimes it may be impossible to know which came first—a cardiac arrest and then hypothermia or vice versa. In those situations, it is prudent to attempt resuscitation. Although a cutoff of 50°F (10°C) for possible survival of accidental hypothermia has been proposed, no compelling evidence or consensus exists that there is any single reasonable temperature below which a human cannot survive. However, there are clear physiologic signs that indicate a patient is “cold and dead” with no chance of resuscitation. The Wilderness Medical Society (WMS) includes in such criteria obvious fatal injuries (such as decapitation, open head injuries with loss of brain matter, truncal transection, incineration) or a chest wall that is so stiff that compressions are not possible. It is worth noting that, according to the 2014 WMS practice guidelines, fixed, dilated pupils, apparent rigor mortis, and dependent lividity are *not* contraindications for resuscitation of severely hypothermic patients. Follow your local protocols regarding resuscitation.

Emergency Medical Care of Local Cold Injuries

The emergency treatment of local cold injuries in the field should include the following steps:

1. Remove the patient from further exposure to the cold.
2. Handle the injured part gently, and protect it from further injury.

3. Administer oxygen, if this was not already done during the primary survey.
4. Remove any wet or restrictive clothing over the injured part.

If there is no chance of reinjury or if transport to the ED will be substantially delayed, consider active rewarming if local protocols allow, or contact medical control for direction. With frostnip, contact with a warm object may be all the patient needs; you can use your hands, your breath, or the patient’s own body. During rewarming, the affected part will often tingle and become red. With immersion foot, remove wet shoes, boots, and socks, and rewarm the foot gradually, protecting it from further cold exposure. Next, splint the extremity, and cover it loosely with a dry, sterile dressing. Never rub injured tissues, which could cause further damage. Do not re-expose the injury to the cold.

With a late or deep cold injury, such as frostbite, remove any jewelry or other potentially restrictive items from the injured part, and cover the injury loosely with a dry, sterile dressing. Do not break blisters or rub or massage the area. Do not apply heat or rewarm the part. Unlike frostnip and trench foot, rewarming of the frostbitten extremity is best accomplished under controlled circumstances in the ED. You can cause further injury to fragile tissues by attempting to rewarm a frostbitten part. Never apply something warm or hot, such as the exhaust from the ambulance engine or, even worse, an open flame. Do not allow the patient to stand or walk on a frostbitten foot. Splinting a frostbitten extremity may also help prevent secondary injury by limiting use.

Evaluate the patient’s general condition for the signs or symptoms of systemic hypothermia. Support the vital functions as necessary, and transport the patient promptly to the hospital.

If prompt hospital care is unavailable and medical control instructs you to institute rewarming in the field, use a warm-water bath. Immerse the frostbitten part in water with a temperature between 102°F and 104°F (38.9°C and 40°C). Check the water temperature with a thermometer before immersing the limb, and recheck it frequently during the rewarming process. The water temperature should never exceed 105°F (40.6°C). Stir the water continuously. Ensure the frostbitten part does not rest against the side of the warm container. Keep the frostbitten part in the water until it feels warm and

sensation has returned to the skin. Dress the area with dry, sterile dressings, placing them also between injured fingers or toes. Expect the patient to report severe pain. You may consider administering nitrous oxide or calling for paramedic backup to administer analgesics.

Never attempt rewarming if there is any chance that the part may freeze again before the patient reaches the hospital. Some of the most severe consequences of frostbite, including gangrene and amputation, have occurred when parts were thawed and then refrozen.

Cover the frostbitten part with soft, padded, sterile cotton dressings. If blisters have formed, do not break them. Remember, you cannot accurately predict the outcome of a case of frostbite early in its course. Even body parts that appear gangrenous may recover following proper emergency and hospital treatment.

Cold Exposure and You

As an AEMT, you are also at risk for hypothermia if you work in a cold environment. If cold-weather search-and-rescue operations are a possibility in your assigned areas, you should receive survival training and precautionary tips. You should be thoroughly familiar with local conditions. Be aware of existing and potential weather conditions, and stay abreast of changes that are forecast for the area. Make sure to wear proper clothing whenever appropriate. Your vehicle, too, must be properly equipped and maintained for a cold environment. As with so many hazards, you cannot help others if you do not practice self-protection. Never allow yourself to become a casualty!

Safety

Do not become a victim! You cannot help others if you do not protect yourself.

Heat Exposure

Normal body temperature is 98.6°F (37°C). Complicated regulatory mechanisms keep this internal temperature constant, regardless of the ambient temperature. In a hot environment or

during vigorous physical activity, when the body itself produces excess heat, it will try to rid itself of the excess heat. The body does this by a process known as thermolysis. The two most efficient methods to decrease heat are sweating (and evaporation of the sweat) and dilation of peripheral blood vessels, which brings warm blood to the skin's surface (causing flushing) to increase the rate of heat radiation. In addition, of course, the person who becomes overheated can remove clothing and seek a cooler environment.

Ordinarily, the heat-regulating mechanisms of the body work very well, and people are able to tolerate substantial temperature changes. When the body is exposed to or generates more heat energy than it can lose because of inadequate thermolysis, hyperthermia can result. Hyperthermia is a high core temperature, usually 101°F (38.3°C) or higher.

Pathophysiology

When the body's mechanisms to decrease body heat are overwhelmed and the body is unable to tolerate the excessive heat, illness develops. High air temperature can reduce the body's ability to lose heat by radiation; high humidity reduces the ability to lose heat through evaporation. Another contributing factor is vigorous exercise, during which the body can lose more than 1 L of sweat per hour, causing loss of fluid and electrolytes. Signs of thermolysis include diaphoresis, increased skin temperature, and flushing. Signs of severe heat illness include altered mentation and altered levels of consciousness. The patient may also present with signs of dehydration. Illness from heat exposure can cause the following problems:

- Heat cramps
- Heat exhaustion
- Heatstroke

All three forms of heat illness may be present in the same patient because untreated **heat exhaustion** may progress to heatstroke. Heatstroke is a life-threatening emergency.

Persons at greatest risk for heat illnesses are children; geriatric patients; people with heart disease, chronic obstructive pulmonary disease (COPD), diabetes, dehydration, and obesity; and people with limited mobility. The autonomic neuropathy in diabetes interferes with vasodilation and perspiration

and may interfere with thermoregulatory input, predisposing people with diabetes to heat illnesses. Older people, newborns, and infants exhibit poor thermoregulation. Alcohol and certain drugs, including medications that dehydrate the body (such as diuretics) or decrease the ability of the body to sweat (such as antihistamines), also make a person more susceptible to heat illnesses.

Other contributing factors to heat illnesses include the length of exposure, intensity of exposure, and the environment itself. Ambient environmental conditions, such as humidity and wind, have a major role as well. This also includes indoor conditions.

Preventive measures to protect from heat emergencies include maintaining an adequate fluid intake, acclimatizing to the environment, and limiting exposure. Thirst is not an adequate indicator of dehydration.⁷ People working outside in high temperatures should drink water continually to replace what is lost through perspiration. In addition, the body adapts to the environment by excreting less sodium through perspiration, although continued exposure to air conditioning blunts the body's adaptation response.⁷ This sodium retention increases fluid volume in the body and decreases the chances of dehydration. Spending time outdoors in the early morning or late evening when temperatures and humidity are lower, as opposed to the middle of the day, can also decrease a patient's risk.

The following subsections discuss the major types of heat illnesses (TABLE 34-2).

Words of Wisdom

Keeping yourself hydrated while on duty is very important, especially during periods of heavy exertion or when working in the heat. Drink at least 3 L of water per day and more when exertion or heat is involved. The color of urine (usually darker with dehydration) and frequency of urination correlate directly with the body's fluid level.

Heat Cramps

Heat cramps are painful muscle spasms that occur after vigorous exercise. They do not occur only when it is hot outdoors. They may be seen in factory workers and even well-conditioned athletes. A study of US college football players showed a twofold increase in sweat sodium losses in athletes susceptible to heat cramps.⁸ The exact cause of heat cramps is not well understood. It is known that sweat produced during strenuous exercise, particularly in a warm environment, causes a change in the body's balance of electrolytes. The result may be a loss of essential electrolytes from the cells. Dehydration may also have a role in the development of muscle cramps. Large amounts of water can be lost from the body as a result of excessive sweating. This loss of water may affect muscles that are being stressed and cause them to spasm.

Heat cramps usually occur in the legs or abdominal muscles. When the abdominal muscles

TABLE 34-2 Comparing Conditions Resulting From Heat Stress

Variable	Heat Cramps	Heat Exhaustion	Heatstroke
Pathophysiology	Sodium and water loss	Sodium and water loss, hypovolemia	Failure of heat-regulating mechanisms
Mental and neurologic status	Normal	Normal or mild confusion	Altered, delirium, seizures
Temperature	May be mildly elevated	Usually mildly elevated	Usually >104°F (40°C)
Skin	Cool, moist	Pale, cool, moist	Dry, hot, but sweating may persist, especially with exertional heatstroke
Muscle cramping	Severe	May or may not be present	Absent

are involved, the pain and muscle spasm may be so severe that the patient appears to have an acute abdominal condition. If a patient with a sudden onset of abdominal cramps has been exercising vigorously in a hot environment, suspect heat cramps.

Heat Exhaustion

Heat exhaustion, also called heat prostration or heat collapse, is the most common illness caused by heat. It is the result of the body losing so much water and so many electrolytes through very heavy sweating that hypovolemia (fluid depletion) occurs. For sweating to be an effective cooling mechanism, the sweat must be able to evaporate from the body. People standing in the hot sun, particularly those wearing several layers of clothing, such as sports fans or parade watchers, may sweat profusely but experience little body cooling. High humidity will also decrease the amount of evaporation that can occur.

People working or exerting themselves in poorly ventilated areas are unable to release heat through convection. Thus, people who work or exercise vigorously and those who wear heavy clothing in a warm, humid, or poorly ventilated environment are particularly susceptible to heat exhaustion.

The signs and symptoms of heat exhaustion and those of associated hypovolemia are as follows:

- Onset while working vigorously or exercising in a hot, humid, or poorly ventilated environment and sweating heavily
- Onset, even at rest, in the older and infant age groups in hot, humid, and poorly ventilated environments or extended time in hot, humid environments. People who are not acclimatized to the environment may also experience onset at rest.
- Cold, clammy skin with ashen pallor
- Dry tongue and thirst
- Dizziness, weakness, or faintness, with accompanying nausea or headache. Muscle cramping may also be present, including abdominal cramping.
- Normal vital signs, although the pulse is often rapid and the blood pressure may be low
- Normal or slightly elevated body temperature; on rare occasions, as high as 104°F (40°C)

In heat exhaustion, there may be a subtle increase in core body temperature with some

neurologic deficit. Symptoms may be solely a result of dehydration combined with overexertion. The result is orthostatic hypotension. Symptoms generally resolve with rest and supine positioning. Fluids and elevation of the legs are also beneficial. Symptoms that do not resolve with rest and positioning may be a result of the increased core body temperature and are predictive of impending heatstroke and must be treated aggressively.

Heatstroke

Heatstroke, the least common but most serious illness caused by heat exposure, occurs when the body is subjected to more heat than it can effectively remove, and normal mechanisms for getting rid of the excess heat are overwhelmed. The body temperature then rises rapidly to the level at which tissues are destroyed, with substantial neurologic deficit. Organ damage occurs in the brain, liver, and kidneys. Heatstroke is a profound emergency, with mortality rates as high as 10% in patients who receive timely treatment and 30% to 80% in patients who are untreated or who receive delayed treatment.⁹

Heatstroke can develop in patients during vigorous physical activity or when they are outdoors or in a closed, poorly ventilated, humid space. It also occurs during heat waves among people (particularly older people) who live in buildings with no air conditioning or with poor ventilation. It may also develop in children who are left unattended in a locked car on a hot day.

Many patients with heatstroke have hot, dry, flushed skin because their sweating mechanism has been overwhelmed and they are severely dehydrated. However, early in the course of heatstroke, the skin may be moist or wet because of residual sweat from earlier perspiration. For this reason, do not rule out heatstroke if the patient's skin is still moist. Keep in mind that a patient can have heatstroke even if still sweating. This presentation is often seen in endurance athletes, military personnel, or emergency providers who wear personal protective equipment, such as firefighters, SWAT (special weapons and tactics) team members, or hazmat (hazardous materials) workers. The minute someone is detected to be having a heat injury, consider that other personnel wearing similar gear or performing similar duties are likely to also have heat injury. The body temperature rises rapidly

in patients with heatstroke and can rise to 106°F (41.1°C) or higher. As the body core temperature rises, the patient's level of consciousness falls.

Often, the first sign of heatstroke is a change in behavior. However, the patient can quickly become unresponsive. Seizure activity may also be noted. The pulse is usually rapid and strong at first, but as the patient becomes increasingly unresponsive, the pulse becomes weaker and the blood pressure falls. The respiratory rate increases because the body is attempting to compensate. One of the telltale signs you should be acutely aware of is when your patient no longer perspires, which means the body has lost its thermoregulatory mechanism. If you are perspiring in the environment, your patient should also be perspiring.

Two types of heatstroke are distinguished: classic and exertional. Classic heatstroke commonly presents in people with chronic illnesses. There is an increased core body temperature because of deficient thermoregulatory function. Predisposing conditions include age, diabetes, and other medical conditions. Hot, red, dry skin is common in these patients. Exertional heatstroke commonly presents in people who are in good general health but have an increased core body temperature because of overwhelming heat stress, which may be caused by excessive ambient temperature, excessive exertion, prolonged exposure, or poor acclimatization. Moist, pale skin is common in these patients.

Recovery from heatstroke depends on the speed with which treatment is administered, so you must be able to identify this condition quickly. Emergency treatment has one objective: get the body temperature down to normal quickly and by any means available.

Assessment of Heat Injuries

Scene Size-up

As part of your scene size-up, perform an environmental assessment. How hot is it outside? How hot is it in the room where your patient is located? How well is the patient tolerating the heat? Dispatch may report the call initially as a medical or trauma emergency. The heat illness may only be secondary. Approach the scene looking for hazards as well

as clues as to what may have caused your patient's emergency. If you anticipate a prolonged scene time, protect yourself from the heat and remember to stay hydrated. Use appropriate standard precautions. Long-sleeved shirts and long pants may be uncomfortable in warm weather; however, they can help protect you from being splashed by blood or other fluids.

As you observe the scene, look for indicators of the MOI. For example, you arrive on the scene at a shopping mall to find an older man with a decreased level of consciousness inside a parked vehicle on a warm, humid, sunny day. The MOI for this patient is sitting in a warm environment under direct sunlight with no ventilation.

Heat emergencies commonly occur in the context of athletic events and practices, often with athletic trainers present. In those instances, you may find the patient submerged in a cold-water immersion bath inside the athletic training room. It is harmful to allow heat to persist for any amount of time; therefore, cooling prior to transport is indicated if facilities such as an ice bath are available. If the patient is placed in a cold-water immersion bath on your arrival, monitor the patient in the water, and assist as necessary. Do not remove the patient until the temperature has normalized to the appropriate level, between 101°F and 102°F (38.3°C and 38.9°C). Do not overcool the patient. Overcooling can result in shivering, which generates more heat. Monitor the patient closely. While you wait, consider consulting medical control or calling for paramedic intercept or backup as these patients are susceptible to cardiac dysrhythmias and may benefit from cardiac monitoring.

Primary Survey

As you approach your patient, observe how the patient interacts with you and the environment. A heat illness may be the primary problem or it may simply be aggravating a medical or trauma condition. Remember, prolonged heat exposure may stress the heart, causing a heart attack. Use this initial interaction to guide you in assessing for immediate life threats and related problems. Perform a rapid full-body scan, and avoid tunnel vision.

Assess the patient's mental status using the AVPU scale. Gathering clues about the patient's

mental status may identify the severity of your patient's condition. The more altered the patient's mental status is, the more serious the heat problem.

Assess the patient's airway and breathing, and treat any life threats, such as exsanguinating hemorrhage. Unless the patient is unresponsive, the airway should be patent. Nausea and vomiting, however, may occur. Position the patient to protect the airway as necessary. If the patient is unresponsive, be cautious how you open the airway; consider spinal precautions if trauma is a possibility. Breathing will be fast, depending on the patient's core temperature, but should otherwise be adequate. Providing oxygen to the patient will assist with the perfusion of body tissues and may decrease nausea. If your patient is unresponsive, insert an airway and provide bag-mask device ventilations according to protocol. Call early for paramedic backup if you feel a more definitive airway is needed.

Assess the patient's circulation by palpating a pulse and feeling the skin. If the pulse is adequate, assess the patient for perfusion and bleeding. Assess the patient's skin condition carefully (**TABLE 34-3**). Treat the patient aggressively for shock by removing the patient from the heat and positioning the patient as dictated by local protocol to improve circulation. If the patient is bleeding, bandage according to protocol.

If your patient has any signs of heatstroke (high temperature; red, dry skin; altered mental status; tachycardia; poor perfusion), then transport without delay to the closest appropriate facility, but begin aggressive cooling en route using whatever means are at your disposal.

TABLE 34-3 Skin Condition

Skin Condition	Indicates
Moist, pale, cool skin	Excessive fluid and salt loss
Hot, dry skin	Body is unable to regulate core temperature
Hot, moist skin	Body is unable to regulate core temperature

© Jones & Bartlett Learning.

History Taking

After the life threats have been managed during the primary survey, investigate the chief complaint. Obtain a medical history and be alert for specific signs and symptoms such as the absence of perspiration, decreased level of consciousness, confusion, muscle cramping, nausea, and vomiting. Obtaining a thorough patient history of the present illness can help differentiate between a fever and a heat emergency.

Obtain a SAMPLE history, noting any activities, conditions, or medications that may predispose a patient to dehydration or heat-related problems. Patients with inadequate oral intake or who are taking diuretics may have difficulty tolerating exposure to heat. Many medications used by geriatric patients affect how well they tolerate heat. Be thorough in your questioning. Determine your patient's exposure to heat and humidity and activities prior to the onset of symptoms.

Secondary Assessment

As always, use the secondary assessment to uncover injuries that may have been missed during the primary survey, and remember that you may not have time to conduct a secondary assessment in critical patients.

If your patient is unresponsive, perform a physical examination of the entire body looking for problems or explanations of what is wrong. Obtain the patient's vital signs, including a blood glucose level, to help understand the severity of the emergency.

If the patient is alert, perform a focused assessment. Exposure to heat has substantial effects on the metabolism, muscles, and cardiovascular system. Assess the patient for muscle cramps or confusion. Examine the patient's mental status, and obtain the patient's vital signs.

Pay special attention to the patient's skin temperature, turgor, and level of moisture. Skin turgor is the ability of the skin to resist deformation. It is tested by gently pinching skin on the forearm or back of the hand; in older patients, the abdomen or chest are better locations to test. Normally the skin will quickly flatten out. If the patient is dehydrated, the skin will remain tented (poor

Special Populations

When testing skin turgor of an older patient, remember to gently pinch the skin on the trunk of the body because the extremities normally have poor turgor.

skin turgor). Also, perform a careful neurologic examination.

Patients with hyperthermia will often be tachycardic and tachypneic. As long as they maintain a normal blood pressure, their bodies will compensate for the fluid loss. After their blood pressure begins to fall, it indicates they are no longer able to compensate for fluid loss and are going into shock. Your assessment of the patient's skin will help determine the severity of the emergency. For example, in heat exhaustion, the skin temperature may be normal or may even be cool and clammy; however, in heatstroke, the skin is hot.

Check the patient's temperature with a thermometer, depending on protocol. Your unit's equipment may include disposable or oral thermometers with disposable covers, or forehead scanning thermometers. Some agencies provide tympanic/ear thermometers. You may not use these devices routinely, so become familiar with how they work. Keep in mind that that oral temperature can be misleading if the patient just ingested a cool drink. In patients with a heat-related illness, monitoring of pulse oximetry is also indicated.

Reassessment

Watch your patient's condition carefully for deterioration. Any decline in level of consciousness is an ominous sign. Monitor the patient's vital signs at least every 5 minutes. Evaluate the effectiveness of your interventions. Be careful not to cause shivering when cooling down a patient who is experiencing a heat emergency. Shivering generates more heat and can occur when cooling is not monitored closely.

Inform the staff at the receiving facility early on that your patient is experiencing heatstroke because additional resources may be required. Document the weather conditions and the activities the patient was performing prior to the emergency in your patient care report.

Emergency Medical Care for Heat Emergencies

Heat Cramps

Take the following steps to treat heat cramps in the field.

1. Promptly remove the patient from the hot environment, including direct sunlight, a source of radiant heat gain. Loosen any tight clothing.
2. Administer high-flow oxygen if indicated (the patient shows signs of hypoxia or respiratory distress) if this was not already done as part of the primary survey.
3. Rest the cramping muscles. Have the patient sit or lie down until the cramps subside.
4. Replace fluids by mouth if protocol allows. Use water or a diluted (half-strength) balanced electrolyte solution, such as a sports drink. In most cases, plain water is the most useful. Do not give salt tablets or solutions that have a high salt concentration. The patient already has an adequate amount of electrolytes circulating; they are just not distributed properly. With adequate rest and fluid replacement, the body will adjust the distribution of electrolytes, and the cramps will disappear.
5. Cool the patient with cool water spray or mist, and add convection to the cooling method by manually or mechanically fanning the patient.

When the heat cramps are gone, the patient may resume activity. For example, an athlete can return to play after the heat cramps have disappeared. However, heavy sweating may cause the cramps to recur. The best preventive and treatment strategy is hydration by drinking sufficient quantities of water.

If the cramps do not go away after these measures, initiate an IV line and transport the patient to the hospital. If you are uncertain that the patient's cramps were caused by the heat or you note anything out of the ordinary, contact medical control or transport the patient to the hospital.

Heat Exhaustion

To treat the patient with heat exhaustion, follow the steps in **SKILL DRILL 34-1**. The treatment of heat exhaustion is aimed at removing the patient from exposure to heat and urgently reversing the increase in body temperature through active cooling efforts.

Skill Drill 34-1 Treating for Heat Exhaustion

Step 1

Promptly remove the patient from the hot environment, preferably into the back of the air-conditioned ambulance. If outdoors, move out of direct sunlight. Remove any excessive layers of clothing, particularly around the head and neck.

Step 2

Administer oxygen if indicated and if this was not already done as part of the primary survey. If the patient has an altered mental status, check the blood glucose level.

Cool the patient with misting and administration of ice packs to the trunk of the patient's body. Use an ice bath or similar facility if available, per local protocol. Encourage the patient to lie down. Loosen any tight clothing, and cool the patient by manual or mechanical fanning.

Step 3

If the patient is fully alert, encourage the patient to sit up and slowly drink up to 1 L of water, as long as nausea does not develop. Never force fluids by mouth on a patient who is not fully alert, or allow drinking while supine, because the patient could aspirate the fluid into the lungs. If the patient does become nauseated, transport the patient on the left side to prevent aspiration.

Gain IV access, and administer normal saline fluid boluses of 20 mL/kg as needed if the patient is nauseated or unable to take fluid by mouth.

Step 4

Transport the patient on the left side if you think the patient may be nauseated, but make certain that the patient is secured.

If an ice bath or similar facility is available, provide cold-water immersion to the patient if allowed per local protocol. Cold-water (ice bath) immersion is recommended for patients with a core temperature of 104°F (40°C) or an altered mental status.

In most cases, measures undertaken to cool the patient will reverse the symptoms, causing the patient to feel better within 30 minutes; however, you should prepare to transport the patient to the hospital for more aggressive treatment, especially in the following circumstances:

- The symptoms do not clear up promptly.
- The level of consciousness decreases.
- The body temperature remains elevated.
- The person is very young, is older, or has any underlying medical condition, such as diabetes or cardiovascular disease.

Heatstroke

Recovery from heatstroke depends on the speed with which treatment is administered, so you must be able to identify this patient quickly. As mentioned, the goal of emergency treatment is to lower the body temperature by any means available. Take the following steps when treating a patient with heatstroke:

1. Move the patient out of the hot environment and into the ambulance.
2. Set the air conditioning to maximum cooling.
3. Remove the patient's clothing.
4. Administer oxygen if indicated, if this was not already done as part of the primary survey. If needed, assist the patient's ventilations with a bag-mask device and appropriate airway adjuncts as per your protocol. Call for paramedic backup if a definitive airway is needed, but never delay transport to do so. Provide cold-water immersion in an ice bath, if possible. Cooling should begin immediately and continue en route to the hospital (**FIGURE 34-10**). If it is not possible to cool en route and cold-water immersion is available at the scene, continue cold-water immersion at the scene until the core body temperature is between 101°F and 102°F (38.3°C and 38.9°C). This is the only time you should consider delaying transport for a patient with possible heatstroke. Consult medical control for advice in any instance where you are remaining on

FIGURE 34-10 As part of the treatment of heatstroke, if consistent with local protocol, immerse the patient in an ice water bath if one is available.

© Toni L. Sandys/Washington Post/Getty Images.

scene to provide active cooling for a patient with heatstroke prior to initiating transport.

5. Cover the patient with wet towels or sheets, or spray the patient with cool water and fan the patient to quickly evaporate the moisture on the skin.
6. Obtain IV access, and administer a 20-mL/kg bolus of an isotonic crystalloid solution, repeating as needed to maintain adequate perfusion and alleviate symptoms of dehydration.
7. Provide immediate transport to the hospital.
8. Notify the hospital as soon as possible so that the staff can prepare to treat the patient immediately on arrival.

Special Populations

Remember that the aging process alters the body's ability to compensate for its surroundings. Temperature-related emergencies can develop in older people over time, even in indoor environments that may not seem uncomfortable to you. Be vigilant for temperature-related illnesses.

Words of Wisdom

Do not cool a patient to the point of shivering or you will increase rather than decrease the body temperature. Ice packs and cold-water immersion may produce reflex vasoconstriction and shivering because of the effect on peripheral thermoreceptors. Reflex hyperthermia results from overcooling, because shivering produces heat.

Water Emergencies

Drowning

Drowning is the process of experiencing respiratory impairment from **submersion** or immersion in liquid. Some agencies may still use the term *near drowning* to refer to a patient who survives, at least temporarily (24 hours), after suffocation in water or other liquids; the current term is *submersion*. Patients with submersion injury can die of secondary complications (such as pneumonia) that occur beyond 24 hours. According to the US Centers for Disease Control and Prevention (CDC), 46,419 drowning deaths were recorded between 1999 and 2010 in the United States, yielding an average of 3,868 deaths per year, or an average of approximately 10 deaths per day.¹⁰ In the United States, drowning is the second leading cause of injury-related death among children younger than 15 years and is the leading cause of death in the age group 1 to 4 years, with 443 deaths in 2018 alone.^{11,12} Alcohol consumption, preexisting seizure disorders, geriatric patients with cardiovascular disease, and unsupervised access to water are among the major risk factors.

Drowning is often the last in a cycle of events caused by panic in the water. It can happen to anyone who is submerged in water for even a short time. Struggling toward the surface or the shore, the person becomes fatigued or exhausted, which leads the person to sink even deeper. However, drowning also occurs in mop buckets, puddles, bathtubs, and other places where the person is not completely submerged. Small children can drown in only a few inches of water if left unattended.

Inhaling very small amounts of fresh or salt water can severely irritate the larynx, sending the muscles of the larynx and the vocal cords into spasm, called **laryngospasm**. The typical person experiences this to a mild degree when a small amount of a liquid is inhaled and the patient coughs and seems to be choking for a few seconds. This is the body's attempt at self-preservation because laryngospasm prevents more water from entering the lungs. In severe cases such as water submersion, however, the patient's lungs cannot be ventilated because substantial laryngospasm is present. Instead, progressive hypoxia occurs until the patient becomes unresponsive. At this point, the spasm relaxes, making rescue breathing possible. Of course, if the patient has not already been removed from

Special Populations

As a person ages, the body can lose the ability to respond to the environment. Older adults undergo changes in their ability to compensate for low or high ambient temperatures. For example, if the ambient temperature rises from 85°F to 94°F (29.5°C to 34.5°C), the older adult may not recognize the change or be able to compensate for it. Therefore, unless the person is accustomed to the heat, heatstroke can develop relatively quickly.

Shivering, a common effect of hypothermia, is the body's attempt to maintain heat. However, because of a decrease in muscle mass or tone, the hypothermic geriatric patient may not shiver. Furthermore, a decrease in muscle mass and body fat means that there is less insulation and protection from the cold. Because of the body's altered response to heat loss and its ability to gain heat, the health care provider might not suspect or report hypothermia. In caring for the geriatric patient in cold climates, be sure to protect the patient against unwanted heat loss. Cover all exposed areas with loose-fitting blankets. Pay particular attention to protecting the patient's head because heat loss from the head and neck is substantial.

Because of reduced circulation to the skin, heat loss via conduction, convection, and radiation is substantially lower. Additionally, the aging process alters the patient's ability to perspire; therefore, heat loss through evaporation is reduced. Because the older patient cannot disperse heat effectively, classic heatstroke can develop rapidly. Typically, the older adult will not go through an initial stage of heat exhaustion. During the summer, you should be acutely aware of the potential for heatstroke and factors that can predispose a patient to heat illness. Factors that increase the possibility of heatstroke include medications, diabetes, alcohol abuse, malnutrition, parkinsonism, hyperthyroidism, and obesity.

Both hypothermia and hyperthermia can appear in older patients in environmental settings that are subtle. These problems are commonly found when an older person has cost concerns about heating or cooling their home and thus keeps the heat turned down in the winter or does not use air conditioning in hot weather. Thermal emergencies can develop over time for older persons in these indoor urban environments that may not seem uncomfortable to you.

the water, the patient may now inhale deeply, and more water may enter the lungs.

Hypothermia is also a major consideration in submersion. Heat loss is rapid, particularly if the

patient is actively flailing about, which expends a lot of energy. However, hypothermia may also be beneficial. The body's **diving reflex**, discussed later, may slow metabolism to the point of protecting vital organs, such as the brain, heart, lungs, and kidneys. Hypoxia is always the first concern, but all submersion victims should be treated for hypothermia.

Diving Emergencies

Most serious water-related injuries are associated with dives, with or without **SCUBA** (self-contained underwater breathing apparatus) gear. (SCUBA gear is a system that delivers air to the mouth and lungs at atmospheric pressures that increase with the depth of the dive.) Some of these injuries are related to the nature of the dive; others result from panic. Panic is not restricted to the person who is frightened by water. It can even happen to an experienced diver or swimmer.

Words of Wisdom

All submersion patients should be transported for evaluation.

There are more than 3.5 million recreational SCUBA divers in the United States, in addition to people engaged in diving for commercial and military purposes.¹³ Medical emergencies relating to SCUBA diving techniques and equipment are becoming increasingly common.

General Pathophysiology: Physical Principles of Pressure Effects

Pressure, which is defined as force per unit area, may be expressed in several ways. The weight of air at sea level, for example, can be expressed as 14.7 pounds per square inch (psi), as 760 mm Hg, or as 1 atmosphere absolute (ATA). The third measurement, ATA, is most commonly used in diving medicine. Because water is much denser than air, relatively small changes in depth produce large changes in pressure. For every 33 feet of seawater (fsw), the pressure increases 1 ATA. The depth of the dive can be used to estimate the pressure to which the diver was exposed: at sea level, the pressure is

1 ATA; at a depth of 33 fsw, the pressure is 2 ATA; at 66 fsw, it is 3 ATA; and so forth. Most SCUBA diving is done at depths between 30 and 60 fsw (2 to 3 ATA).

Liquids such as water are not compressible; that is, their volumes do not change with pressure. Because the body and its tissues are composed primarily of water, their volumes are not substantially affected by the pressure changes experienced in descent or ascent through water. However, gas-filled organs are another matter, because gases are compressible and follow several physical laws:

- *Boyle's law* states that at a constant temperature, the volume of a gas is inversely proportional to its pressure (if you double the pressure on a gas, you halve its volume):

$$PV = k$$

where P is pressure, V is volume, and k is a constant. As a diver descends (and the pressure goes up), gas volume is reduced; as the diver ascends (pressure goes down), gas volume increases. As shown in **FIGURE 34-11**, this effect is most extreme near the water's surface. This law explains the **barotrauma** that can occur in gas-filled spaces in the body (including lungs, gastrointestinal tract, sinuses, and parts of the ear).

FIGURE 34-11 Boyle's law: As a bubble descends through water, its volume changes in inverse proportion to the ambient pressure.

© Jones & Bartlett Learning.

- *Dalton's law* deals with the pressures exerted by mixtures of different gases. Dalton's law states that each gas in mixture exerts the same partial pressure that it would exert if it were alone in the same volume and that the total pressure of a mixture of gases is the sum of the partial pressures of all gases in the mixture. Thus, for fresh air:

$$P_{\text{total}} = P_{\text{O}_2} + P_{\text{CO}_2} + P_{\text{N}_2}$$

When total pressure increases, the partial pressure of each gas increases proportionally. This law helps explain nitrogen narcosis, oxygen toxicity, and the dangers of contamination in pressurized breathing systems. Because the relative percentage of each gas remains constant at different pressures, it also explains why pulse oximetry readings in divers with nitrogen narcosis remain unaffected.

- *Henry's law* states that the amount (concentration) of gas dissolved in a liquid is directly proportional to the partial pressure of the gas above the liquid:

$$P = kC$$

where P is partial pressure of the gas above the liquid, k is a constant, and C is concentration of gas in the liquid. A classic example of this law is when a sealed bottle that has dissolved carbon dioxide is opened. The opened bottle allows carbon dioxide to escape, lowering the partial pressure (P) of the gas. This forces the concentration of carbon dioxide in the soda to decrease as well, and the extra carbon dioxide escapes as bubbles. This law explains **decompression sickness** (the **bends**).

Fresh air is composed of about 79% nitrogen and 21% oxygen. Nitrogen is an inert fat-soluble gas (it prefers to dissolve in fatty or lipid-rich tissues, including the nervous system). Nitrogen in the body follows the laws just described. Per Boyle's law, the volume of nitrogen decreases as pressure increases (during descent) and its volume increases as pressure decreases (during ascent), resulting in barotrauma. Per Dalton's law, the partial pressure of nitrogen increases as total pressure increases. Nitrogen at a high enough partial pressure becomes an anesthetic, resulting in nitrogen narcosis at depths of approximately 100 fsw.

Per Henry's law, as pressure decreases during ascent, nitrogen comes out of solution in the blood and may cause bubbles in tissue, resulting in decompression sickness, or the bends. Oxygen also follows these laws, and it can cause oxygen toxicity at depths via the same mechanism as nitrogen narcosis. However, because oxygen is taken up and metabolized by the body, oxygen does not contribute to decompression sickness. To avoid the problems listed here, commercial divers use a decompression schedule to allow gases time to equilibrate. Recreational divers usually adhere to a no-decompression limit (a table outlining safe times at various depths) so they do not have to decompress on surfacing. Use of enriched Nitrox gas, which is a gas with a lower nitrogen and a higher oxygen concentration, decreases the risk of nitrogen narcosis and decompression illness, but it increases the risk of oxygen toxicity. Dive tables and dive computers provide guidelines for divers regarding when to take decompression stops during the dive, but they are not perfect. Even if divers follow recommended tables or use the appropriate gas mixture, they may still be at risk for any type of diving injury.

Words of Wisdom

As a diver descends, the gases in the body take up less space, allowing for more gas within the body. As the diver ascends, the gas bubbles get larger, and, unless the diver continually breathes out to rid the lungs of the excess gas, gas-filled organs may rupture.

General Assessment: Diving History

It is important for you to obtain as many details as you can about the dive and the onset of the patient's symptoms. As you obtain the diving history, it is helpful to use a special form that records the following information:

- When did symptoms start (during ascent or descent)? Decompression sickness will usually manifest within the first hour of surfacing and usually within 24 hours. If the patient flew after diving, then consider decompression sickness up to 72 hours afterward. Symptoms occurring within 10 minutes of surfacing suggest **air embolism**, especially when they are accompanied by a loss of consciousness.

- What type of diving was done, and what type of equipment was used?
- What type of tank was used (compressed air or a Nitrox system [combination of nitrogen and oxygen] with distinctive yellow and green stripes on the tank or a different mixed gas)?
- Where is the diving site, and what was the water temperature?
- How many dives were made during the past 72 hours, and what were the depth, bottom time, and surface interval for each?
- Was a dive computer used?
- Were safety stops used?
- Were there any attempts at in-water decompression (considered risky)?
- Were there any dive complications?
- What were pre-dive and post-dive activities?

Descent Emergencies

Diving injuries are separated into three phases of the dive: descent, bottom, and ascent.

The major problem divers encounter during descent is barotrauma (squeeze). This injury results from a pressure imbalance between gas-filled spaces inside the body and the external atmosphere. Barotrauma can result from two different mechanisms: compression of gases within body spaces during descent or expansion of gases within those spaces during ascent (discussed later). Barotrauma can affect any gas-filled space in the body, including the sinuses, the inner and middle ears, and even teeth. Some body cavities cannot adjust to the increased external pressure of the water, resulting in severe pain. Usually, the pain caused by these problems forces the diver to return to the surface to equalize the pressures, and the problem clears up by itself. A diver who continues to report pain, particularly in the ear, after returning to the surface should be transported to the hospital. **TABLE 34-4** summarizes the types of barotrauma.

A person who is SCUBA diving is generally protected from barotrauma by breathing compressed air that matches the pressure of the surrounding

TABLE 34-4 Diving Injuries (Types of Barotrauma)

Mechanisms and Pathophysiology	Body Region	Condition	Clinical Features	Treatment
During descent: compression of gas in closed spaces	Ear	External ear squeeze (<i>barotitis externa</i>)	Otalgia, bloody otorrhea	Keep ear canal dry; no swimming or diving until healed
		Middle ear squeeze (<i>barotitis media</i>)	Severe ear pain, tympanic membrane can rupture; emesis, vertigo, nystagmus; self-limited facial nerve palsy	Decongestants; IV antiemetic (call for paramedic backup for administration if needed); no diving until healed
		Inner ear squeeze	Tinnitus, vertigo, hearing loss; emesis, pallor, diaphoresis	Decongestants; IV antiemetics (call for paramedic backup for administration); surgical repair
	Paranasal sinuses	Sinus squeeze	Severe pain over affected sinuses and upper teeth, epistaxis	Topical and oral decongestants
	Face	Face mask squeeze	Ecchymoses and petechiae of skin beneath face mask; scleral/conjunctival hemorrhage	Cold compresses, prevent by forced exhalation through nose

Mechanisms and Pathophysiology	Body Region	Condition	Clinical Features	Treatment
During ascent: expansion of gas in closed spaces	Gastrointestinal tract	"Gas in gut" (<i>aerogastralgia</i>)	Colicky belly pain, belching, flatulence; rare pneumoperitoneum	Rare reports of rupture; usually, no care needed
	Lungs	Pulmonary barotrauma "burst lung," POPS	Dyspnea, dysphagia, hoarseness, substernal pain; subcutaneous emphysema around neck; pneumothorax, syncope	100% oxygen; call for paramedic backup to decompress tension pneumothorax
		Air embolism (complication of POPS)	Altered mental status, vertigo, dizziness, seizures, dyspnea, pleuritic chest pain, sudden loss of consciousness on surfacing; sudden death	100% oxygen; transport supine; if air embolism suspected, place in left lateral recumbent position; hyperbaric therapy
Decompression sickness	Skin		Pruritus, subcutaneous emphysema, swelling, rashes	100% oxygen; observe for complications
	Joints and muscles	Bends ("pain-only bends")	Arthralgias, especially in elbows and shoulders, relieved by pressure	100% oxygen, observe
	Cerebrum		Multiple sensory and motor disturbances	100% oxygen, hyperbaric therapy; IV fluids
	Cerebellum	The "staggers"	Unsteadiness, incoordination, vertigo	100% oxygen, hyperbaric therapy; IV fluids
	Spinal cord		Paraplegia, paraparesis, bladder dysfunction (inability to void), back pain	100% oxygen, hyperbaric therapy; IV fluids
	Lungs	Venous air embolism (the "chokes")	Chest pain, cough, dyspnea, signs of pulmonary embolism	100% oxygen, hyperbaric therapy; IV fluids
Dissolved nitrogen	Central nervous system	Nitrogen narcosis ("rapture of the deep")	Symptoms like those of alcohol intoxication	Controlled ascent to shallower water
Hyperventilation before dive	Central nervous system	Shallow water blackout (in breath-hold dives)	Loss of consciousness just before reaching surface	100% oxygen; assisted breathing

Abbreviations: IV, intravenous; POPS, pulmonary overpressurization syndrome

environment. Thus, as long as the air-filled cavities of the body can equilibrate freely, they will not implode. This no longer holds true if there is an obstruction, such as with a sinus or ear infection.

As the diver ascends and the ambient pressure decreases, the gases within the body's air-filled spaces expand. Similar to barotrauma during descent, this commonly affects the ears and sinuses. In one common scenario in which a diver has used decongestants before a dive, the medication may wear off before ascent. The increased mucosal swelling allows air to become trapped in the sinuses and ears, creating a reverse squeeze in which the increasing pressure cannot equalize during ascent. Symptoms are identical to those observed during descent.

A person with a perforated tympanic membrane (ruptured eardrum) may develop a special problem while diving. If cold water enters the middle ear through a ruptured eardrum, the diver may lose balance and orientation. As a result, the diver may ascend too quickly, causing further problems.

Injuries at Depth

Nitrogen narcosis ("rapture of the deep" or "narc'ed") is a state of altered mental status caused by breathing compressed nitrogen-containing air at depth. The human body does not use nitrogen for metabolism; thus, in a breathing gas mixture, nitrogen dilutes the concentration of oxygen. Nitrogen, which makes up 79% of fresh air, will also make up 79% of compressed air according to Dalton's law. When the pressure increases, the partial pressure of nitrogen increases as well. At a partial pressure of about 3.2 ATA, reached at about 100 feet (30 m), nitrogen begins to have anesthetic properties, and divers may begin to feel the effects of nitrogen narcosis. It becomes more pronounced at 150 fsw and is why sport divers should not use compressed air for dives of greater than 120 feet (37 m).

Ascent Emergencies

Most of the serious injuries associated with diving are related to ascending from the bottom and are referred to as ascent problems. These emergencies usually require aggressive resuscitation. Two particularly dangerous medical emergencies are air embolism and decompression sickness (also called the bends).

Pulmonary Overpressurization Syndrome (POPS)

A more dangerous form of barotrauma can occur when divers fail to exhale during an ascent, and pressure in the lungs is increased. The lung volume of SCUBA divers who have inhaled to their total lung capacity at a depth of 33 fsw (1 ATA) doubles by the time divers reach the surface if they hold their breath during ascent. This is likely to occur in an emergency ascent, for example, when divers panic due to difficulty with their equipment and give in to the instinctive impulse to hold their breath under water. The result is one of the worst forms of barotrauma of ascent: **pulmonary overpressurization syndrome (POPS)**, also known as "burst lung." It can cause pneumothorax, mediastinal and subcutaneous emphysema, alveolar hemorrhage, and a lethal air embolism, discussed in the next section. Because the relative pressure and volume changes are greatest near the surface of the water, a small overpressurization, such as that produced by breath holding for the last 6 feet (2 m) of ascent, can be sufficient to rupture alveoli. For that reason, all diving students are trained to exhale constantly as they are ascending to vent air from their lungs. People with COPD and asthma are at a slightly increased risk owing to their already altered air movement dynamics.

When alveoli rupture, the signs and symptoms depend partly on where the escaping air ends up. Most commonly, it leaks into the mediastinum and beneath the skin, causing mediastinal and subcutaneous emphysema. The patient may report a sensation of fullness in the throat, pain on swallowing (odynophagia), dyspnea, or substernal chest pain. The patient may be hoarse or have a brassy quality to the voice. Physical examination may reveal palpable subcutaneous air above the clavicles. Sometimes a crunching noise that is synchronous with the heartbeat may be audible by auscultation (called Hamman sign). Another less-common result of alveolar rupture is pneumothorax; therefore, you should always look for unequal breath sounds, low pulse oximetry values, and hyperresonance on the affected side of the chest.

The prehospital treatment of a patient with pulmonary barotrauma depends, at least in terms of urgency, on whether the patient has an air embolism (discussed next). A diver with only pneumomediastinum and subcutaneous emphysema

will most likely be managed symptomatically in the hospital. A pneumothorax may require needle decompression or a chest tube. In the field, provide 100% oxygen (by nonrebreathing mask. If you must bag the patient, be careful; do not give positive end-expiratory pressure to a patient with POPS!) because it increases oxygen's partial pressure and may decrease bubble size and speed up "off-gassing."

Air Embolism

The most dangerous, and most common, emergency in SCUBA diving is air embolism, a condition involving bubbles of air in the blood vessels. An air embolism may occur on a dive as shallow as 6 feet (2 m). The problem starts when the diver holds the breath during a rapid ascent. The air pressure in the lungs remains at a high level, while the external pressure on the chest decreases. As a result, the air inside the lungs expands rapidly, causing the alveoli in the lungs to rupture and forcing air into the bloodstream. The air released from this rupture can cause the following injuries:

- Air may enter the pleural space and compress the lungs (pneumothorax).
- Air may enter the mediastinum (the space within the thorax that contains the heart

and great vessels), causing a condition called pneumomediastinum.

- Air may enter the bloodstream and create bubbles of air in the vessels called air emboli.

Pneumothorax and pneumomediastinum both result in pain and severe dyspnea. An air embolus will act as a plug and prevent the normal flow of blood and oxygen to a specific part of the body. The brain and spinal cord are the organs most severely affected by air embolism because they require a constant supply of oxygen.

The following are potential signs and symptoms of air embolism:

- Blotching (mottling of the skin)
- Froth (often pink or bloody) at the nose and mouth
- Severe pain in muscles, joints, or abdomen
- Dyspnea
- Localized pleuritic (sharp) chest pain
- Dizziness, nausea, and vomiting
- Dysphasia (difficulty speaking)
- Cough
- Cyanosis
- Difficulty with vision
- Paralysis and/or coma
- Irregular pulse and even cardiac arrest

YOU are the Provider

Part 3

You find no signs of trauma on the patient, and as soon as the police officer returns with the stretcher, you gently lift the patient onto the stretcher and secure him. As soon as the patient is placed into the warmed ambulance, you instruct your partner to quickly remove all of the patient's clothing, wipe him down in an attempt to dry him, and place several blankets on top of him to try to warm his core temperature. Recognizing that this patient requires supplemental, warmed oxygen, you place him on a nonrebreathing mask at 15 L/min. You advise your partner that this patient requires rapid, but smooth, transport to the local ED.

Recording Time: 8 Minutes

Respirations	14 breaths/min, clear
Pulse	46 beats/min, irregular
Skin	Cold
Blood pressure	Unable to obtain
Oxygen saturation (SpO ₂)	95% on 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. How can warmed, supplemental oxygen be provided to a hypothermic patient?
6. What are some potential complications of rough handling of hypothermic patients?

Decompression Sickness

Decompression sickness, commonly called the bends, occurs when bubbles of gas, especially nitrogen, obstruct the blood vessels. This condition results from too rapid an ascent from a dive, too long of a dive at too deep a depth, or repeated dives within a short period. During the dive, nitrogen that is being breathed dissolves in the blood and tissues because it is under pressure. When the diver ascends, the external pressure is decreased, and the dissolved nitrogen forms small bubbles within the tissues. These bubbles can result in problems similar to those that occur in air embolism (blockage of tiny blood vessels, depriving parts of the body of their normal blood supply), but severe pain in certain tissues or spaces in the body is the most common problem.

The most striking symptom is abdominal and/or joint pain so severe that the patient literally doubles over, or bends. Dive tables and small diving computers are available to calculate and record the proper rate of ascent from a dive, including the number and length of pauses that a diver should make (staged ascent). However, even divers who stay within these limits can experience the bends.

Even after a safe dive, decompression sickness can occur from driving a car up a mountain or flying in an unpressurized airplane that climbs too rapidly to a great height. However, the risk of this diminishes after 24 to 48 hours. The problem is exactly the same as ascent from a deep dive: a sudden decrease of external pressure on the body and release of dissolved nitrogen from the blood that forms bubbles of nitrogen gas within the blood vessels.

You may find it difficult to distinguish between air embolism and decompression sickness. In general, air embolism occurs immediately on return to the surface, whereas the symptoms of decompression sickness may not occur for several hours. The emergency treatment is the same for both. It consists of basic life support (BLS) including oxygen administration, monitoring, and transport, followed by recompression in a **hyperbaric chamber**, a chamber or a small room that is pressurized to a level higher than atmospheric pressure (**FIGURE 34-12**). Recompression treatment allows the bubbles of gas to dissolve into the blood and equalizes the pressures inside and outside the lungs. After these

FIGURE 34-12 A hyperbaric chamber, usually a small room, is pressurized to a level higher than atmospheric pressure and used in the treatment of decompression sickness and air embolism.

Courtesy of Perry Baromedical Corporation.

pressures are equalized, gradual decompression can be accomplished under controlled conditions to prevent the bubbles from reforming.

Water Rescue

Before you can assess or treat a patient in water, rescue and removal from the water must occur. You must ensure the safety of rescue personnel and request additional rescue resources, as appropriate, before a water rescue can begin. If the patient is alert and still in the water, you should perform a water rescue. An old saying sums up the basic rule of water rescue: “Reach, throw, and row, and only then go.” **FIGURE 34-13** sums up the basic rule of water rescue:

1. First, try to reach for the patient.
2. If that does not work, then throw the patient a rope, a life preserver, or any floatable object that is available. For example, an inflated spare tire, rim and all, will float well enough to support two people in the water.
3. Next, use a boat if one is available.
4. Do not attempt a swimming rescue unless you are trained and experienced in the proper techniques. Even then, you should always wear a helmet and a personal flotation device (**FIGURE 34-14**).

FIGURE 34-13 Basic rules of water rescue. **A.** Reach for the person from shore. If you cannot reach the person from shore, wade closer. **B.** If an object that floats is available, throw it to the person. **C.** Use a boat if one is available. **D.** If you must swim to the person, use a towel or board for the person to hold onto. Do not let the person grab you.

© Jones & Bartlett Learning.

Too many well-meaning rescuers have become victims while attempting a water rescue. A panicked swimmer will make every effort to remain above water, even if this means submerging the rescuer in the process. In cold climates or cold-water locations,

FIGURE 34-14 When performing a water rescue, you must be properly trained and must wear proper personal protective equipment, including a personal flotation device.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

rapid hypothermia is also a concern for rescuers. Be prepared for this potential event.

The steps for ice rescue are similar and may involve reaching with a pole or ladder or throwing a rope or flotation device. A victim who has fallen through the ice may also be coached into placing the arms out of the water and onto the ice, kicking and rolling out of the water, and crawling to safety.

If you work in a recreation area near lakes, rivers, or the ocean, you should have a prearranged plan for water rescue. For colder areas, a plan for ice rescue is also necessary. This plan should include access to and cooperation with local providers who are trained and skilled in water rescue; these providers should help to develop the protocols for water rescue. Because the success of any water rescue depends on how rapidly the patient is removed from the water and ventilated, make sure you always have immediate access to personal flotation devices and other rescue equipment. Survival rates drastically decline the longer a victim is immersed. Cold-water drowning survival rates are somewhat higher.

Spinal Injuries in Submersion Incidents

Submersion incidents may be complicated by spinal fractures and spinal cord injuries. You must assume that spinal injury exists with the following conditions:

- The submersion has resulted from a diving mishap or fall from a substantial height.

- The patient is unresponsive, and no information is available to rule out the possibility of a neck injury.
- The patient is responsive but reports weakness, paralysis, numbness, or tingling in the arms or legs.
- You suspect the possibility of a spinal injury despite what witnesses say.

Most spinal injuries in diving incidents affect the cervical spine. When spinal injury is suspected, the neck must be protected from further injury. This means that you will have to stabilize the suspected injury while the patient is still in the water. To stabilize a suspected spinal injury in the water, follow the steps in **SKILL DRILL 34-2**.

Skill Drill 34-2 Stabilizing a Suspected Spinal Injury in the Water

Step 1

Turn the patient supine. Two rescuers are usually required to turn the patient safely, although in some cases one rescuer will suffice. Always rotate the entire upper half of the patient's body as a single unit. Twisting only the head, for example, may aggravate any injury to the cervical spine.

Step 2

Restore the airway and begin ventilation. Immediate ventilation is the primary treatment of all drowning patients as soon as the patient is faceup in the water. Use a pocket mask if available. Have the other rescuer support the head and trunk as a unit while you open the airway and begin artificial ventilation.

Step 3

Float a buoyant backboard under the patient as you continue ventilation.

Step 4

Secure the head and trunk to the backboard to stabilize the cervical spine. Do not remove the patient from the water until this is done.

Skill Drill 34-2 Stabilizing a Suspected Spinal Injury in the Water (continued)

Step 5

Remove the patient from the water, on the backboard.

Step 6

Cover the patient with a blanket. Give oxygen if the patient is breathing spontaneously. Begin CPR if there is no pulse. Effective chest compressions are extremely difficult to perform when the patient is still in the water, so remove the patient as quickly as possible. Consider paramedic backup for endotracheal intubation to maintain the airway if needed.

Recovery Techniques

On occasion, you may be called to the scene of a drowning and find that the patient is not floating or visible in the water. An organized rescue effort in these circumstances calls for providers who are experienced with recovery techniques and equipment, including snorkel, mask, and SCUBA gear (**FIGURE 34-15**).

Assessment of Drowning and Diving Emergencies

Scene Size-up

In managing water emergencies, your standard precautions should include gloves and eye protection at a minimum. Check for hazards to your crew. Never drive through moving water—a small amount can cause the vehicle to be swept away. Use extreme caution when driving through standing water. Never

FIGURE 34-15 Never attempt a deep-water rescue without proper training and equipment.

© Mark C. Ide.

attempt a water rescue without proper training and equipment. Call for additional resources early.

If your patient is still in the water, look for the best, safest means of removal. This may require additional help from search and rescue teams or

special extrication equipment. Trauma and spinal stabilization must be considered when the scene is a recreational setting. Check for additional patients based on where and how the emergency occurred. Finally, as you observe the scene, look for indicators of the MOI.

Primary Survey

Use your evaluation of the patient's chief complaint to guide you in your assessment of life threats, addressing exsanguinating hemorrhage first, and determine whether spinal stabilization is necessary. Pay particular attention to chest pain, dyspnea, and complaints related to sensory changes when a diving emergency is suspected. Determine the patient's level of consciousness using the AVPU scale. Be suspicious of drug and alcohol use and the effects on the patient's level of consciousness.

Standard measures should be employed for any patient found or injured while in the water. Begin with opening the airway and assessing breathing in unresponsive patients. Consider the possibility of spinal trauma, and take appropriate actions as discussed earlier. The airway may be obstructed with water. Suction according to protocol if the patient has vomited or pink, frothy secretions are found in the airway. Foam in the mouth and airway of submersion patients is mostly surfactant and debris and does not need to be cleared; it can be pushed back into the lungs during ventilation and will be reabsorbed.¹⁴ Do not spend substantial amounts of time trying to clear foam from the airway. Provide ventilations with a bag-mask device for inadequate breathing. Use an airway adjunct to facilitate bag-mask device ventilations as necessary.

If the patient is responsive, provide high-flow oxygen with a nonrebreathing mask and if there is no risk of spinal injury, position the patient to

protect the airway from aspiration in the event of vomiting. When necessary, begin artificial ventilation as soon as possible, even before the patient is removed from the water.

Obtaining and continually monitoring breath sounds in drowning patients is a key part of your assessment. Through auscultation, you may hear diminished sounds or even gurgling sounds from the water that has been inhaled. This information and any changes in the patient's breath sounds are important to relay to paramedics who may rendezvous with your unit as well as to the receiving facility.

Words of Wisdom

When a person dives or jumps into extremely cold water, the diving reflex (also known as the mammalian diving reflex), slowing of the heart rate caused by submersion in cold water, may cause immediate bradycardia, a slow heart rhythm.¹⁵ Loss of consciousness and drowning may follow. However, the person may be able to survive for an extended time under water because of a lowering of the metabolic rate and decreased oxygen demand and consumption associated with hypothermia. For this reason, you should continue full resuscitation efforts no matter how long the patient has been submerged.

Check for a pulse. It may be difficult to find a pulse because of constriction of the peripheral blood vessels and low cardiac output resulting in cyanosis. Nevertheless, if the pulse is unmeasurable, then the patient may be in cardiac arrest. Begin CPR with chest compressions, and apply your automated external defibrillator (AED) according to BLS and the International Liaison Committee on Resuscitation (ILCOR) guidelines.

Never give up on resuscitating a cold-water drowning victim. When a person is submerged in water that is colder than body temperature, heat will be conducted from the body to the water. The resulting hypothermia can protect vital organs from the lack of oxygen. In addition, exposure to cold water will occasionally activate certain primitive reflexes, which may preserve basic body functions for prolonged periods.

Evaluate the patient for adequate perfusion, and treat for shock by maintaining normal body temperature and improving circulation through

Words of Wisdom

The patient's breathing or lack of breathing can be a determining factor in submersion time. A patient who was briefly submerged may be coughing if rescued early. The longer the patient is under water, the more water enters the lungs. Respiratory arrest occurs from prolonged submersion.

positioning the patient in the position dictated by local protocol. The patient's skin may be cold to the touch. If the MOI suggests trauma, assess for bleeding and treat appropriately.

Even if resuscitation in the field appears successful, always transport patients to the hospital. Symptoms may not appear for 24 hours or more after resuscitation. Adult respiratory distress syndrome (ARDS) or renal failure may occur after resuscitation. Inhalation of any amount of fluid can result in delayed complications lasting for days or weeks. Patients with decompression sickness and air embolism must be treated in a recompression chamber. If you live in an area with a substantial amount of SCUBA diving activity, you will have transport protocols in this regard. To minimize your scene time, perform your interventions en route to the nearest ED for stabilization.

History Taking

After the life threats have been managed during the primary survey, investigate the chief complaint. Obtain a medical history, and be alert for injury-specific signs and symptoms as well as any pertinent negatives.

Obtain a SAMPLE history with special attention to the dive parameters, including depth, the length of time the patient was under water, the time of onset of symptoms, and previous diving activity. Note any physical activity, alcohol or drug consumption, and other medical conditions. All of these factors may have an effect on the diving or drowning emergency.

Secondary Assessment

If the patient is responsive, focus your physical examination on the basis of the chief complaint and the history obtained. This should include a thorough examination of the patient's lungs, including breath sounds.

Serious drowning situations typically result in an unresponsive patient. It is important to begin with a rapid full-body scan in these situations to look for hidden life threats and potential trauma, even if trauma is not suspected. A SCUBA diver with problems should be given a rapid full-body scan for indications of the bends or an air embolism. Focus

on pain in the joints and the abdomen. Pay attention to whether your patient is getting adequate ventilation and oxygenation, and check for signs of hypothermia. Obtain a baseline Glasgow Coma Scale score to assess the patient's neurologic status and thinking, and be sure to reassess throughout patient care.

Time and personnel permitting, complete a detailed full-body exam en route to the hospital. A careful examination may reveal additional injuries not initially observable. Monitor the patient for respiratory, circulatory, and neurologic compromise. A careful distal circulatory, sensory, and motor function examination will be helpful in assessing the extent of the injury. Assess for peripheral pulses, skin color and discoloration, itching, pain, and paresthesias (numbness and tingling).

Check the patient's vital signs, including pulse rate, quality, and rhythm. Pulse and blood pressure may be difficult to palpate in a patient with hypothermia. Check carefully for both peripheral and central pulses, and listen over the chest for a heart-beat if pulses are weak. Check the respiratory rate, quality, and rhythm, and listen to breath sounds. Assess and document pupil size and reactivity. Also check blood glucose levels.

Although it is a valuable tool, oxygen saturation readings may produce a false low reading because of hypoperfusion of the patient's monitoring finger. Shivering also can interfere with obtaining an accurate reading because of excessive movement.

Assessment Pearls

- Whether you are dealing with a heat-related or a cold-related emergency, the first step is getting the patient out of the adverse environment.
- Do not cool hyperthermic patients to the point of shivering. Shivering generates heat and will result in a reflex hyperthermia.
- Reverse triage for lightning strikes!
- Patients with heatstroke may still be diaphoretic from prior exertion. Do not discount the severity just because the skin is moist.
- Position patients with a possible pulmonary embolism on their left side with the head down.
- Never apply ice to a snakebite! Cold causes vasoconstriction and will force the venom into the central circulation.

Reassessment

Repeat the primary survey. Reassess vital signs and the chief complaint. Are the airway, breathing, and circulation still adequate? Recheck patient interventions. Are your treatments still effective?

The condition of patients who have experienced submersion in water may deteriorate rapidly because of pulmonary injury, fluid shifts in the body, cerebral hypoxia, and hypothermia—call early for paramedic backup if a definitive airway is needed. Patients with pneumothorax, air embolism, or decompression sickness may decompensate quickly. Assess your patient's mental status constantly, and assess vital signs at least every 5 minutes. Pay particular attention to respirations and breath sounds.

Document the circumstances of the drowning and extrication. The receiving facility personnel will need to know how long the patient was submerged, the temperature of the water, the clarity of the water, and whether there was any possibility of cervical spine injury.

If you respond to a diving accident, the receiving facility personnel will also need a complete dive profile to properly treat your patient. This information may be available in a dive log, on a dive computer, or from the patient's diving partners. If possible, bring all of the diver's equipment to the hospital. It will be helpful in determining the cause of the accident. Be sure to document the disposition of this equipment—what happened to it and who it was left with.

Emergency Care for Drowning or Diving Emergencies

After removing the patient from the water and addressing concerns related to the ABCs and possible spinal injury, make sure that the patient is kept warm, especially after cold-water immersion. Provide blankets and protection from the environment as needed. Obtain IV access to be used as a medication route even if the patient does not need fluid resuscitation, but do not delay transport by attempting IV access.

When treating responsive patients who are suspected of having air embolism or decompression sickness, follow these accepted treatment steps:

1. Remove the patient from the water. Try to keep the patient calm.

2. Administer oxygen via nonrebreathing mask or bag-mask device assist.
3. Place the patient in a left lateral recumbent position with the head down.
4. Consider the possibility of pneumothorax, and monitor the patient's breath sounds for development of a tension pneumothorax.
5. Provide prompt transport to the ED or to the nearest recompression facility for treatment.

Injury from decompression sickness is usually reversible with proper treatment. However, if the bubbles block critical blood vessels that supply the brain or spinal cord, permanent central nervous system injury may result. Therefore, the key in emergency management of patients with these serious ascent problems is to recognize that an emergency exists and treat and transport as soon as possible.

Words of Wisdom

Do not perform manual abdominal thrusts (Heimlich maneuver) to remove water from the lungs because they may displace water from the stomach into the lungs, increasing the risk of pneumonitis and subsequent lung infections. Suction may be used to clear the airway. Early advanced airway placement is indicated if BLS airway interventions fail.

Submerged Vehicle Incidents

According to the WMS, Project ALIVE, the Wilderness EMS Medical Director Course, and drowning experts, the current best evidence suggests that the safest time to escape from a submerging vehicle is immediately after it enters the water, during the initial floating phase, which usually lasts 60 seconds or less.¹⁶ A sequence of steps has been established to ensure that occupants in a submerging vehicle prioritize egress strategies: seat belts, windows, children, out. These steps indicate that seat belts should be removed (one's own and anyone else unable to do it themselves), followed by opening or breaking windows, releasing children (oldest to youngest), then immediately exiting the vehicle.

Almost every year, deaths occur while callers are on the phone with emergency medical dispatchers because they are not instructed to immediately exit

the vehicle. At least one major prehospital dispatch system has changed its protocols to address this. Many people drown in submerging vehicles without contacting 9-1-1 and without exiting the vehicle. One reason is a prevailing myth that victims in a submerging vehicle should allow the passenger compartment to fill with water before attempting egress. This action is not evidence-based and is extremely dangerous.

When arriving on the scene of an actively submerging vehicle, attempt to remove the passengers from the vehicle as quickly as possible, usually through the rear window after breaking it. Attempt this only if you have adequate training for water entry and the circumstances are reasonable from a scene safety perspective.

Other Water Hazards

Pay close attention to the body temperature of a person who is rescued from cold water. Treat hypothermia caused by immersion in cold water the same way you treat hypothermia caused by cold exposure. Prevent further heat loss from contact with the ground, stretcher, or air, and transport the patient promptly.

A person swimming in shallow water may experience **breath-holding syncope**, a loss of consciousness caused by a decreased stimulus for breathing. This happens to swimmers who breathe in and out rapidly and deeply before entering the water in an effort to expand their capacity to stay underwater. Whereas this technique increases the swimmer's oxygen level, the hyperventilation involved lowers the carbon dioxide level. Because an elevated level of carbon dioxide in the blood is the strongest stimulus for breathing, the swimmer may not feel the need to breathe even after using up all the oxygen in the lungs. The emergency treatment for a patient with breath-holding syncope is the same as that for drowning or submersion (**FIGURE 34-16**).

Injuries caused by boat propellers, sharp rocks, water skis, or dangerous marine life may be complicated by immersion in cold water. In these cases, remove the patient from the water, taking care to protect the spine, and administer oxygen. Apply dressings and splints if indicated, and monitor the patient closely for any signs of immersion or cold injury.

FIGURE 34-16 Even the best swimmer can panic and become a victim. Only properly trained personnel should attempt a rescue.

Courtesy of Rhonda Hunt.

You should be aware that a child who is involved in a drowning or submersion may be the victim of child abuse. Although it may be difficult to prove, such incidents should be handled according to laws regarding suspected child abuse.

Prevention

Each year, many small children drown in residential pools.¹⁷ Appropriate precautions can prevent most immersion incidents. All pools should be surrounded by a fence that is at least 6 feet (2 m) high, with slats no farther apart than 3 inches (8 cm) and self-closing, self-locking gates. The most common problem is lack of adult supervision, even when a child is unattended for only a few seconds. Approximately 70% of all teenage and adult drownings are associated with alcohol use.¹⁷ As a health care professional, you should be involved in public education efforts to make people aware of the hazards of swimming pools and water recreation.

High Altitude

High altitudes can cause dysbarism injuries. Dysbarism injuries are any signs and symptoms caused by the difference between the surrounding atmospheric pressure and the total gas pressure in various tissues, fluids, and cavities of the body. Altitude illnesses occur when an unacclimated person is exposed to diminished oxygen pressure in the air at

high altitudes. These illnesses affect the central nervous system and pulmonary system and range from the common acute mountain sickness to the rare deaths from high-altitude cerebral edema (HACE) and high-altitude pulmonary edema (HAPE).

Acute mountain sickness is caused by diminished oxygen pressure in the air at altitudes above 5,000 feet (1.5 km), resulting in diminished oxygen in the blood (hypoxia). It strikes those who ascend too high too fast and those who have not acclimatized to high altitudes. The signs and symptoms include a headache, light-headedness, fatigue, loss of appetite, nausea, difficulty sleeping, shortness of breath during physical exertion, and a swollen face. However, there may be other possible causes for the same symptoms, such as hypoglycemia or carbon monoxide poisoning from a camping stove.

With HAPE, fluid collects in the lungs, hindering the passage of oxygen into the bloodstream. It can occur at altitudes of 8,000 feet (2 km) or greater. The signs and symptoms include shortness of breath, cough with pink sputum, cyanosis, and a rapid pulse.

HACE usually occurs in climbers who climb above 12,000 feet (3.7 km). It may accompany HAPE and can quickly become life threatening. The symptoms of HACE and HAPE may overlap. The signs

and symptoms include a severe, constant throbbing headache; ataxia (lack of muscle coordination and balance); extreme fatigue; vomiting; and loss of consciousness.

In the field, treatment for altitude illness consists of providing oxygen, descending from the height, and transporting the patient. If local protocols allow, continuous positive airway pressure (CPAP) may be very helpful for a patient with respiratory distress from HAPE.

Lightning Injuries

Approximately 49 people die from lightning strikes in the United States each year.¹⁸ Those who do not die from their injuries are left with varied degrees of disability. Most lightning deaths and injuries caused by lightning occur during the summer months when people are enjoying outdoor activities, despite an approaching thunderstorm. Those most commonly struck by lightning include boaters, swimmers, and golfers. Any type of activity that exposes the person to a large, open area increases the risk of being struck by lightning.

Lightning strikes when a massive discharge of electricity occurs between two bodies that have different charges—for example, between a

YOU are the Provider

Part 4

As you begin your transport, you establish a large-bore IV and infuse a 250-mL bolus of warmed normal saline to try to increase his blood pressure. You reassess the patient and find him responsive to deep, painful stimuli only but still able to maintain a patent airway. Your partner advises that you are about two blocks from the hospital, and you begin preparations to turn over care. After you are at the ED, you give your report to the nurse and complete your patient care report.

8. Why should active rewarming not be attempted in this patient?

thundercloud and the ground. The stream of current takes the path of least resistance from its origin to its destination. If any object projects above the surface of the earth that is a better conductor of electricity than the air (such as a building, a light pole, an antenna, a flagpole, or a tree) that object will “attract” the lightning bolt.

Whether lightning injures or kills depends on whether a person is in the path of the lightning discharge. The current associated with the lightning discharge travels along the ground. Although some people are injured or killed by a direct lightning strike, many victims are indirectly struck when standing near an object that has been struck by lightning, such as a tree, and the lightning spreads out from that point (splash effect).

A person need not sustain a direct hit from lightning to be injured; in fact, most victims are not struck directly. Much more commonly, the victim is splashed by lightning striking a nearby tree or other projecting object, resulting in an arc-type or flash burn that leaves a characteristic “feathering” pattern on the skin (**FIGURE 34-17**). Ground current produced by lightning striking the ground near the victim can also cause severe injury and accounts for incidents in which there are multiple casualties in an extended area, such as on a golf course or in an open field.

Lightning carries enormous electrical power. Its energy can reach 100 *million* volts, and peak currents can be in the range of 200,000 amps. Unlike other high-voltage electric current, the electricity from lightning is *direct*—not alternating—current, and the duration of exposure is measured in milliseconds. Thus, lightning injuries tend to resemble blast injuries more than they do high-voltage injuries, with damage occurring to the tympanic membranes of the ears and air-containing internal organs. Many reports of lightning strikes indicate victims’ clothes were “blown off” of their bodies. Muscle damage may occur, and the release of myoglobin from injured muscle may jeopardize the kidneys.

For the cardiovascular system, lightning acts as a cosmic defibrillator, delivering a massive direct-current countershock that depolarizes the entire heart. The heart may resume beating spontaneously shortly after the shock or after 5 cycles (30:2) or approximately 2 minutes of CPR that is started immediately. Because respiratory arrest is

FIGURE 34-17 An arc-type burn resulting from a nearby lightning strike may leave a characteristic feathering pattern on the skin.

Reprinted from Journal of Plastic, Reconstructive & Aesthetic Surgery, 61/1, Ajay L. Mahajan, Ruchika Rajan, Padraic J. Regan, Lichtenberg figures: cutaneous manifestation of phone electrocution from lightning, Pages 111-113., Copyright (2008), with permission from Elsevier.

apt to persist in patients who have been struck by lightning, continued ventilatory support may be required. The phenomenon of someone regaining a pulse after a lightning strike and having respiratory arrest is known to result in a secondary cardiac arrest if left untreated. The central nervous system is almost invariably affected by a lightning strike. Temporary paralysis of the legs has occurred, and permanent paralysis and quadriplegia have been reported in a few cases.

Words of Wisdom

Touching the victim of a lightning strike is not hazardous; contrary to what your grandparent may have told you, electricity does not remain within the body of a person who has been hit by lightning.

During your assessment, look for not only the entrance wound but also the exit wound. The exit wound does not necessarily occur on the same side of the body. Additionally, because the duration of a lightning strike is short, skin burns are usually superficial; full-thickness (third-degree) burns are rare. Lightning injuries are categorized as being mild, moderate, or severe:

- **Mild.** Loss of consciousness, amnesia, confusion, tingling, and other nonspecific signs and symptoms. Burns, if present, are typically superficial.
- **Moderate.** Seizures, respiratory arrest, cardiac standstill (asystole) that spontaneously resolves, and superficial burns.
- **Severe.** Cardiopulmonary arrest. Because of the delay in resuscitation, often the result of remote locations, many of these patients do not survive.

Despite the unique circumstances surrounding a lightning strike, the immediate threats to life are the same as those caused by a high-voltage power line injury: airway obstruction, respiratory arrest, and cardiac arrest.

Emergency Medical Care for Lightning Injuries

When you reach the scene of a lightning strike, all the usual priorities apply, but there are two special considerations to keep in mind.

First, if the electrical storm is ongoing, your first priority is to get any patients and rescuers to a safe place, preferably indoors, or at least inside the ambulance. Lightning *can* strike twice in the same place. If you are in an open area and adequate shelter is unavailable, it is important to recognize the signs of an impending lightning strike and take immediate action to protect yourself. If you suddenly feel a tingling sensation or your hair stands on end, the area around you has become charged, a sure sign of an imminent lightning strike. Curl up in a ball and squat; make yourself as small a target as possible. If you are standing near a tree or other tall object, move away as fast as possible, preferably to a low-lying area. Lightning has an affinity for objects that project from the ground (ie, trees, fences, buildings) and that are good conductors.

Words of Wisdom

In a lightning strike with multiple victims, priority goes to the victims who are not breathing.

Second, be aware that a lightning strike is apt to injure more than one person. Therefore, the first thing you need to do on arrival at the scene—before you leave the safety of the ambulance—is to perform a rapid size-up of the entire scene to determine the number of patients.

The process of triaging multiple victims of a lightning strike is different from the conventional triage methods used during a mass-casualty incident. When a person is struck by lightning, respiratory or cardiac arrest, if it occurs, usually occurs immediately. Those who are alert following a lightning strike are much less likely to develop delayed respiratory or cardiac arrest; most of these people will survive. Therefore, you should focus your efforts on those who are in respiratory or cardiac arrest. This, process, called **reverse triage**, differs from conventional triage, where such patients would ordinarily be classified as deceased.

After safety and triage have been addressed, you may assess and treat the patient or patients. Start CPR when necessary. Carry out the primary survey as usual. When establishing an airway, keep in mind the possibility of cervical spine injury, and do not hyperextend the neck; instead, use the jaw-thrust maneuver.

Patients with cardiac arrest caused by a lightning strike deserve aggressive, continuing CPR. The chances of a successful resuscitation in such a case are good, even when the patient appears beyond help initially and even when there is a long delay in the return of spontaneous breathing. Minimize the interruption in compressions, and push hard and fast with full chest recoil!

If severe bleeding is present, control it immediately. Because of the massive direct current shock caused by lightning, the patient experiences massive muscle spasms (tetany), which can result in fractures of long bones and spinal vertebrae. Therefore, manually stabilize the patient's head in a neutral inline position, and open the airway with the jaw-thrust maneuver. If the patient is in respiratory

arrest with a pulse, begin immediate bag-mask ventilations with 100% oxygen. If the patient is in cardiac arrest, begin chest compressions immediately, then attach an AED as soon as one is available, and provide immediate defibrillation if indicated.

Words of Wisdom

Cardiac arrest secondary to lightning strike can often be successfully treated with early defibrillation.

If you are unable to effectively ventilate the patient with a bag-mask device, insert an advanced airway device. Insert at least one large-bore IV line and provide crystalloid (ie, normal saline, lactated Ringer) fluid boluses of 20 mL/kg to treat suspected hypovolemia and to promote the excretion of myoglobin, a chemical released by injured muscle that can result in renal damage or failure.

Provide full spinal immobilization and transport the patient to the closest appropriate facility. If CPR or ventilations are not required, address other injuries (ie, splint fractures, dress and bandage burns) and provide continuous monitoring while en route to the hospital. A patient with signs and symptoms of a lightning strike but no obvious life threats should still be transported to the ED for evaluation.

Treatment of lightning injuries can be summarized as follows:

- Make sure the scene is safe. Move the victim to a safer location if necessary.
- Priority for treatment goes to patients who are not breathing.
- Perform CPR as needed. Establish an airway, and take cervical spine precautions.
- Administer supplemental oxygen.
- Insert a large-bore IV catheter and deliver an isotonic crystalloid solution wide open to keep the kidneys flushed out.
- Cover any surface burns with dry, clean dressings.
- Splint fractures.

The best treatment for lightning injuries is prevention, and all health care professionals have a responsibility to educate the public in preventive

TABLE 34-5 Techniques to Avoid Being Struck by Lightning

Rule 1: Don't be the tallest object that is a good conductor. Stay away from the middle of fields; lakes; golf courses; and other large, open areas. If you are stuck in the middle of an open area, try to be as small as you can. Do not hold up an umbrella, golf club, or lightning rod. Do not fly a kite.

Rule 2: Don't stand under or near the tallest object that is a good conductor. Although you do not want to be in the middle of the field, you also do not want to be under the tallest tree, radio antenna, or golf umbrella.

Rule 3: Take shelter in the most substantial structure that you can to remain safe if it is hit by lightning. A large building with a lightning suppression system is the best choice. An enclosed building is better than an open one (eg, shed, lean-to). Close the shelter as much as possible. If in a vehicle, keep the windows rolled up. Lightning tends to flash over the outside of objects (and people). It can travel substantial distances through conductors, however.

Rule 4: Avoid touching good conductors during a lightning storm. Examples of good conductors include plumbing fixtures, fences, and electrical appliances, particularly those connected to wires outside (eg, telephone, TV, computer).

© Jones & Bartlett Learning.

measures. Clearly, the most effective precaution is to come in out of the storm, but that is not always possible. The rules in **TABLE 34-5** can help avoid lightning injuries.

Bites and Envenomations

Spider Bites

Spiders are numerous and widespread in the United States. Many species of spiders can bite people, and most of these spiders are venomous. However, only two in the United States, the female black widow spider and the brown recluse spider, can deliver serious, even life-threatening bites. When you care for a patient who has sustained a spider bite, be alert to the possibility that the spider may still be in the area. Remember that your safety is of paramount importance.

Black Widow Spider

The female black widow spider (*Latrodectus*) is fairly large, measuring approximately 2 inches (5 cm) long with its legs extended. It is usually black and has a distinctive, bright red-orange marking in the shape of an hourglass on its abdomen (**FIGURE 34-18**). The female is larger and more toxic than the male. Black widow spiders are found in every state except Alaska. They prefer dry, dim places around buildings, in woodpiles, and among debris.

The bite of the black widow spider is sometimes overlooked. If the site becomes numb right away, the patient may not even recall being bitten. However, most black widow spider bites cause immediate localized pain and symptoms, including agonizing muscle spasms. In some cases, a bite on the abdomen causes muscle spasms so severe that the patient may be thought to have an acute abdominal condition, such as peritonitis. The main danger with this type of bite, however, comes from the fact that the black widow's venom can damage nerve tissues (it is neurotoxic). Other systemic symptoms include dizziness, sweating, nausea, vomiting, and rashes. Tightness in the chest and difficulty breathing typically develop within 24 hours, as do severe cramps, with boardlike rigidity of the abdominal muscles. Generally, these signs and symptoms subside over 48 hours.

FIGURE 34-18 Black widow spiders are distinguished by their glossy black color and bright red-orange hourglass marking on the abdomen.

© Crystal Kirk/Shutterstock.

If necessary, a physician can administer a specific **antivenin**, a serum containing antibodies that counteract the venom, but because of a high incidence of side effects, its use is reserved for severe bites, for older or extremely feeble people, and for children younger than 5 years. In children, these bites can be fatal. The severe muscle spasms are usually treated in the hospital with IV benzodiazepines such as diazepam (Valium) or lorazepam (Ativan). In general, emergency treatment for a black widow spider bite consists of BLS for the patient in respiratory distress, cleaning the bite with soap and water, and applying an ice pack to the area. Much more often, the patient will only require pain relief. Transport the patient to the ED as soon as possible for treatment. If possible, safely bring the spider to the hospital, or take a photo of the spider with a cell phone and send it to the hospital ahead of time so that it can be definitively identified.

Brown Recluse Spider

The brown recluse spider (*Loxosceles*) is dull brown and, at 1 inch (3 cm), smaller than the black widow (**FIGURE 34-19**). The short-haired body has a violin-shaped mark that is brown to yellow on its back, which is why it is commonly referred to as the “fiddleback” spider. Although it lives mostly in the southern and central parts of the country, the

FIGURE 34-19 Brown recluse spiders are dull brown and have a dark, violin-shaped mark on the back.

Courtesy of Kenneth Cramer, Monmouth College.

brown recluse may be found throughout the continental United States. The spider is named for its tendency to live in dark areas—in corners of old, unused buildings, under rocks, and in woodpiles. In cooler areas, it moves indoors to closets, drawers, cellars, and clothing.

In contrast with the venom of the black widow spider, the venom of the brown recluse spider is not neurotoxic but cytotoxic; that is, it causes severe local tissue damage. Typically, the bite is not painful at first but becomes so within hours. The area becomes swollen and tender and develops a pale, mottled, cyanotic center and possibly a small blister (FIGURE 34-20). Over the next several days, a scab of dead skin, fat, and debris will form and dig into the skin, producing a large ulcer that may not heal unless treated promptly. Transport patients with such symptoms as soon as possible.

Brown recluse spider bites rarely cause systemic symptoms and signs. When they do, provide BLS and prompt transport to the ED. Again, it is helpful if you can identify the spider and either safely bring it to the hospital with the patient, or take a picture of the spider and send it to the hospital ahead of time.

Hymenoptera Stings

Typically, **Hymenoptera** (bees, wasps, ants, and yellow jackets) stings are painful but are not a medical emergency. Remove the stinger and, if still present, the venom sac. This is best done by using a firm-edged item such as a credit card to scrape

FIGURE 34-20 The bite of a brown recluse spider is characterized by swelling, tenderness, and a pale, mottled, cyanotic center. There may also be a small blister on the bite.

Courtesy of Department of Entomology, University of Nebraska.

the stinger and sac off the skin. If you inadvertently squeeze the venom sac while trying to grasp the stinger with tweezers or forceps, you will worsen the patient's exposure by increasing the amount of envenomation. After the stinger is removed, clean thoroughly with soap and water or an anti-septic solution, and treat with cool compresses and elevation.

If the patient is allergic to the venom, then anaphylaxis may occur. The signs and symptoms of anaphylaxis are flushed skin, low blood pressure, difficulty breathing usually associated with reactive airway sounds such as wheezes, or in severe cases diminished or absent breath sounds. The patient can also have swelling to the throat and tongue. This is a dire emergency and can be fatal if not recognized and treated quickly. The patient may develop hives (urticaria) near the site of envenomation or centrally on the body. If anaphylaxis develops, be prepared to administer epinephrine (via an EpiPen or similar auto-injector or subcutaneously). Also be prepared to support the airway and breathing should the patient experience substantial respiratory compromise. Chapter 22, *Immunologic Emergencies*, covers treatment of anaphylaxis.

Snakebites

Snakebites are a global problem. More than 5.4 million snakebites occur annually worldwide, resulting in approximately 81,000 to 137,000 deaths.¹⁹ Approximately 10,000 snakebites occur in the United States every year; approximately 30% of those are venomous.²⁰ However, fatalities from snakebites in the United States are extremely rare, at approximately five per year for the entire country.²¹

Of the approximately 115 different species of snakes in the United States, only 19 are venomous. These include the rattlesnake (*Crotalus*); the copperhead (*Agkistrodon contortrix*), the cottonmouth, or water moccasin (*Agkistrodon piscivorus*); and the coral snakes (*Micrurus fulvius* and *Micruroides euryxanthus*) (FIGURE 34-21). At least one of these venomous species is found in every state except Alaska, Hawaii, and Maine. In general, these creatures are timid. They usually do not bite unless provoked or accidentally injured, such as when they are stepped on. There are a few exceptions to these rules. Cottonmouths are often rather aggressive, and rattlesnakes are easily provoked. Coral snakes,

in contrast, usually bite only when they are being handled.

Most snakebites occur between April and October, when the animals are active, and tend to involve young men who have been drinking alcohol. Texas reports the largest number of bites. Other states with a major concentration of snakebites are Louisiana, Georgia, Oklahoma, North Carolina, Arkansas, West Virginia, and Mississippi. If you work in one of these areas, you should be thoroughly familiar with the emergency care of snakebites. Remember, almost any time you are caring for a patient with a snakebite, another snake, or perhaps the same one, could come along and create a second victim—you. Therefore, use extreme caution on these calls, and be sure to wear the proper protective equipment for the area.

The amount of toxin injected is directly related to toxicity, but often, there is little or no envenomation. In general, only one-third of snakebites result

in substantial local or systemic injuries. Often, envenomation does not occur because the snake has recently struck another animal and temporarily exhausted its supply of venom.

With the exception of the coral snake, venomous snakes native to the United States all have hollow fangs in the roof of the mouth that inject the poison from two sacs at the back of the head. The classic appearance of the venomous snakebite, therefore, is two small puncture wounds, usually approximately 0.5 inch (1 cm) apart, with discoloration and swelling, and the patient usually reports pain surrounding the bite (**FIGURE 34-22**). Nonvenomous snakes can also bite, usually leaving horseshoe-shaped teeth marks. However, some venomous snakes have teeth as well as fangs, making it impossible to determine the type of snake responsible for a given set of teeth marks. Fang marks are a clear indication of a venomous snakebite.

FIGURE 34-22 A snakebite wound from a venomous snake has characteristic markings: two small puncture wounds approximately 0.5 inch (1 cm) apart, discoloration, and swelling.

© American Academy of Orthopaedic Surgeons.

A person who has been bitten by any venomous snake needs prompt transport. Also, notify the hospital as soon as possible if a patient has been bitten by a pit viper or coral snake. Some venoms can cause paralysis of the nervous system, and hospitals may not have appropriate antivenin on hand.

Pit Vipers

Rattlesnakes, copperheads, and cottonmouths are all pit vipers, with triangular-shaped, flat heads (**FIGURE 34-23**). They take their name from the small pits located just behind each nostril and in front of each eye. The pit is a heat-sensing organ that allows the snake to strike accurately at any warm target, especially in the dark when it cannot see through its vertical, slitlike pupils.

The fangs of the pit viper normally lie flat against the roof of the mouth and are hinged to swing back and forth as the mouth opens. When the snake strikes, the mouth opens wide and the fangs extend; in this way, the fangs penetrate whatever the mouth strikes. The fangs are special hollow teeth that act similar to hypodermic needles. They are connected to a sac containing a reservoir of venom, which is attached to a poison gland. The gland itself is a specifically adapted salivary gland, which produces powerful enzymes that digest and destroy tissue. The primary purpose of the venom is to kill small animals and to start the digestive process before they are eaten.

In the United States, the most common form of pit viper is the rattlesnake. Several different species

FIGURE 34-23 Characteristics of pit vipers and nonvenomous snakes. **A.** Pit vipers have vertical pupils, a pit between the eye and the nostril, a single row of teeth, and two erectile fangs. **B.** Nonvenomous snakes have round pupils and often a double row of upper teeth; they do not leave fang marks. An exception is the coral snake, which is a venomous snake with round pupils that does not leave fang marks.

© Jones & Bartlett Learning.

of rattlesnake can be identified by the rattle on the tail. The rattle is composed of numerous layers of dried skin that were shed but failed to fall off, coming to rest against a small knob on the end of the tail. When agitated or endangered, rattlesnakes shake their tails, or rattles, to warn the invader away. Rattlesnakes have many patterns of color, often with a diamond pattern. They can grow to 6 feet (2 m) or more in length.

Copperheads are smaller than rattlesnakes, usually 2 to 3 feet long (60 to 90 cm), with a red-copper color crossed with brown or red bands. These snakes typically inhabit woodpiles and abandoned dwellings, often close to areas of habitation. Although they account for most of the venomous snakebites in the eastern United States, copperhead bites are typically not fatal; however, note that the venom can cause substantial damage to tissues in the extremities.

Words of Wisdom

When treating the victim of a snakebite, use a marker to outline the area of swelling. This will show how much swelling has occurred between the time the patient was picked up and arrived at the ED.

Cottonmouths grow to approximately 4 feet (1 m) in length. Also called water moccasins, these snakes are olive or brown, with black cross-bands and a yellow undersurface. They are water snakes, with a particularly aggressive pattern of behavior. Although deaths from the bites of these snakes are rare, tissue destruction from the venom may be severe. Cottonmouths have been known to strike at their victims from the water.

The signs of envenomation by a pit viper are severe burning pain at the site of the injury, followed by swelling and, in light-skinned people, a blue discoloration (ecchymosis) that signals bleeding under the skin. These signs are evident within 5 to 10 minutes after the bite has occurred, and they spread during the next 36 hours. In addition to destroying tissues locally, the venom of the pit viper can also interfere with the body's blood-clotting mechanisms and cause bleeding at various distant sites. This toxin affects the entire nervous system. Other systemic signs, which may or may not occur, include weakness, nausea, vomiting, vision problems, seizures, sweating, fainting, changes in level of consciousness, and shock. Patient age and size are also factors. The smaller the patient, the more severe the symptoms are likely to be with envenomation. If the patient has no local signs 1 hour after being bitten, envenomation more than likely did not occur. If swelling has occurred, use a marker to mark its edges on the skin. This will allow physicians to assess the timing and extent of the swelling with greater accuracy. Frequently measuring the circumference of the affected extremity will allow you to determine the speed at which swelling is occurring.

Coral Snakes

The coral snake is a small reptile with a series of bright red, yellow, and black bands completely encircling the body. Many harmless snakes have similar coloring (such as the king snake), but only the coral snake has red and yellow bands next to one another, as this helpful rhyme suggests: "Red on yellow will kill a fellow; red on black, venom will lack."

A rare creature that lives in most southern states and in the Southwest, the coral snake is a relative of the cobra. It has tiny fangs and injects the venom with its teeth by a chewing motion, leaving behind one or more puncture or scratch-like wounds. Because of its small mouth and teeth

and limited jaw expansion, the coral snake usually bites its victims on a small part of the body, such as a finger or toe.

Coral snake venom is a powerful toxin that causes paralysis of the nervous system (neurotoxic). Within a few hours of being bitten, a patient will exhibit bizarre behavior, followed by progressive paralysis of eye movements and respiration. Often, there are limited or no local symptoms.

Treatment of Snakebites

The steps for emergency care of a pit viper bite and a coral snakebite are similar.

In treating a snakebite from a pit viper, follow these steps:

1. Calm the patient; assure the person that venomous snakebites are rarely fatal. Have the patient lie supine, and explain that remaining still and calm will slow the spread of any venom through the system. Determine the approximate time of the bite, and document your time en route to a receiving facility. This time from onset to evaluation at the facility is one of the criteria used in grading the severity of the incident and in determining the amount of antivenin to be used.
2. Locate the bite area; clean it gently with soap and water or a mild antiseptic to wash away any poison left on the surface of the skin. *Do not apply ice* to the area because this will cause local vasoconstriction and push the venom farther into the bloodstream. If the patient is hypotensive, then a constricting band may be applied 4 to 6 inches above the bite site if called for by your local protocols. You should be able to slide two fingers underneath the band. Some local protocols do not allow the use of a constricting band in treating snakebites because of the potential of the venom pooling into the localized bite area. This could potentially cause greater damage to the localized area.
3. If the bite occurred on an arm or leg, consider the use of a pressure immobilization bandage of the extremity per local protocol (eg, 40 to 70 mm Hg in the arms and 55 to 70 mm Hg in the legs), and then place the affected extremity below the level of the heart. Pressure is sufficient if the bandage is snug but allows a finger to be slipped under it.

FIGURE 34-24 In a patient with a snakebite, mark the skin to indicate the area that is swollen.

Courtesy of Rhonda Hunt.

FIGURE 34-25 If possible, take the snake with you to the hospital for identification.

Courtesy of Rhonda Hunt.

4. Be alert for an anaphylactic reaction to the venom, and treat with an epinephrine auto-injector, as appropriate.
5. Do not give anything by mouth, and be alert for vomiting.
6. If, as rarely happens, the patient was bitten on the trunk, keep the patient supine and calm and transport as quickly as possible.
7. Monitor the patient's vital signs, and mark the skin with a marker over the area that is swollen, proximal to the swelling, to note whether swelling is spreading (**FIGURE 34-24**).
8. If signs of shock are present, place the patient supine and administer 100% oxygen. Be prepared to assist ventilations if needed. Initiate IV therapy according to local protocols.
9. If the snake has been killed, as is often the case, take it with you, or take a photo on your cell phone, so that physicians can identify it and administer the proper antivenin. Be careful in handling any snake. The fangs of a pit viper are sharp and may scratch your skin, allowing the remaining venom to penetrate. If the snake is still present, you may be able to take a photo of it from a safe distance, but doing so does not warrant exposing yourself to risk.
10. Notify the hospital that you are bringing in a patient who has a snakebite; if possible, describe the snake.
11. Transport the patient promptly to the hospital.
12. Call for paramedic backup if needed.

Words of Wisdom

Evidence of the exact source of an allergic reaction or envenomation may be scarce when you arrive, or bystanders may give you incorrect information. The cause is more likely to pose a risk to responders, and added risk to the patient, if you draw incorrect conclusions about its nature. Keep your eyes and ears open, avoid making unsupported assumptions, and be curious about things that don't quite make sense.

Safety

When treating a snakebite victim, take the snake along to the hospital for identification if it has been killed or take a photo from a safe distance. If you are scratched or punctured by the fangs when handling the snake, you may also be envenomated. Use extreme caution.

Successful treatment for a coral snakebite, either emergency or long term, depends on positive identification of the snake and support of vital central nervous system functions, such as breathing (**FIGURE 34-25**). Antivenin is available for coral snakebites, but most hospitals do not stock it. Therefore, you should notify the receiving hospital of the need for it as soon as possible. Follow the same steps listed for emergency care of a pit viper bite, check the patient's vital signs (particularly

respirations), and continue to monitor them along with neurologic status.

If the patient shows no sign of envenomation, provide BLS as needed, place a sterile dressing over the suspected bite area, and immobilize the injury site. All patients with a suspected snakebite should be taken to the ED, whether they show signs of envenomation or not. Treat the wound as you would any deep puncture wound to prevent infection.

If you work in an area where venomous snakes are known to live, know your local protocol for handling snakebites. There may be specific hospitals where antivenin is more readily available, either in the facility or through zoos, health departments, or other services.

Scorpion Stings

Scorpions are eight-legged arachnids from the biological class Arachnida, with a venom gland and a stinger at the end of their tail (**FIGURE 34-26**). Scorpions live primarily in the southwestern United States and in deserts. With one exception, the sting of scorpions in the United States is usually very painful but not dangerous, causing localized swelling and discoloration. The exception is the *Centruroides sculpturatus*. Although it is found naturally in Arizona and New Mexico, as well as parts of Texas,

FIGURE 34-26 The sting of a scorpion is usually more painful than it is dangerous, causing localized swelling and discoloration.

© Visual&Written SL/Alamy Stock Photo.

California, and Nevada, it may be kept as a pet by anyone. The venom of this particular species may produce a severe systemic reaction that brings about circulatory collapse, severe muscle contractions, excessive salivation, hypertension, seizures, and cardiac failure. Antivenin is available but must be administered by a physician. If you are called to care for a patient with a suspected sting from a *C. sculpturatus* specimen, notify medical control as soon as possible. Administer BLS and provide rapid transport to the ED.

Tick Bites

Found most often on brush, shrubs, trees, sand dunes, or other animals, ticks usually attach themselves directly to the skin (**FIGURE 34-27**). Only a fraction of an inch (approximately 3 mm) long, they can easily be mistaken for a freckle, especially because their bite is not painful. Indeed, the danger with a tick bite is not usually from the bite itself but from the infecting organisms that the tick carries. The most common tickborne diseases are Lyme disease and Rocky Mountain spotted fever; however, other diseases such as ehrlichiosis and tularemia may be important locally. Tickborne diseases are spread through the tick's saliva, which is injected into the skin when the tick attaches itself.

FIGURE 34-27 Ticks typically attach themselves directly to the skin.

© Joao Estevo A. Freitas (jefras)/Shutterstock.

Words of Wisdom

Lyme disease is often mistaken for rheumatoid arthritis, and patients infected may go for long periods without appropriate treatment. It is vital to avoid tunnel vision and obtain a complete history, especially onset of symptoms, when interviewing a patient.

The longer a tick stays embedded, the greater the chance that a disease will be transmitted.

Rocky Mountain spotted fever, which is not limited to the Rocky Mountains, occurs within 7 to 10 days after a bite by an infected tick. Its symptoms include nausea, vomiting, headache, weakness, paralysis, and possibly cardiorespiratory collapse.

Lyme disease has received extensive publicity. It was originally seen only in Connecticut. According to the CDC, Lyme disease has now been reported in all states with the exception of Hawaii.²² It occurs most commonly in the Northeast, the Great Lakes states, and the Pacific Northwest; Pennsylvania reported the largest number of confirmed cases for 2018.²² The first symptoms generally include fever, flulike symptoms, and a rash that may spread to several parts of the body and typically begins approximately 3 days after the bite of an infected tick. The rash may eventually resemble a target or bull's-eye pattern in one-third of patients (**FIGURE 34-28**). After a few days or weeks, painful swelling of the joints, particularly the knees, occurs. Lyme disease may be confused

with rheumatoid arthritis and, like that disease, may result in permanent disability. However, if it is recognized and treated promptly with antibiotics, the patient may recover completely.

Tick bites occur most commonly during the summer months, when people are out in the woods wearing little protective clothing. Transmission of the infection from tick to person takes at least 12 hours, so if you are called to remove a tick, you should proceed carefully and slowly. Do not attempt to suffocate the tick with gasoline or petroleum jelly, or burn it with a lighted match; you will only increase the risk of infection or burn the patient. Using fine tweezers, grasp the tick by the head and pull it gently but firmly straight up so that the skin is tented. Hold this position until the tick releases. Special tweezers are available for this but are unnecessary. This method will usually remove the whole tick. (Partial removal can result in infection.) Cleanse the area with antiseptic, and save the tick in a glass jar or other container so that it can be identified. Do not handle the tick with your fingers. The patient should follow up with a health care provider as soon as possible.

Injuries From Marine Animals

Coelenterates, including the fire coral, Portuguese man-of-war, sea wasp, sea nettles, true jellyfish, sea anemones, true coral, and soft coral, are responsible for more envenomations than any other marine animals (**FIGURE 34-29**). The stinging cells of the coelenterate are called nematocysts, and large animals may discharge hundreds of thousands of them. In light-skinned people, envenomation causes extremely painful red lesions extending in a line from the site of the sting. Systemic symptoms include headache, dizziness, muscle cramps, and fainting.

To treat a sting from the tentacles of a jellyfish, a Portuguese man-of-war, various anemones, corals, or hydras (a type of stinging shrimp), remove the patient from the water and remove the tentacles by scraping them off with the edge of a stiff object such as a credit card. Wash the affected area with vinegar immediately if available for at least 30 seconds to help inactivate the nematocysts. Alcohol may be used but is not as effective. Limit further discharge of nematocysts by avoiding fresh water, wet sand, showers, or careless manipulation of the tentacles.

FIGURE 34-28 The rash associated with Lyme disease has a characteristic bull's-eye pattern.

Keep the patient calm, and reduce motion of the affected extremity. Persistent pain may respond to immersion of the area in hot water (110°F to 115°F [43°C to 46°C]) for 30 minutes. On very rare occasions, a patient may have a systemic allergic

reaction to the sting of one of these animals. Treat such a patient for anaphylactic shock, and provide immediate transport to the hospital. Call for paramedic backup if needed.

Toxins from the spines of urchins; stingrays; and certain spiny fish such as the lionfish, scorpion fish, and stonefish are heat sensitive (**TABLE 34-6**). Therefore, the best treatment for such injuries is to immobilize the affected area and soak it in hot water for 30 minutes. This will often provide dramatic relief from local pain. However, the patient still needs to be transported to the ED because the patient could develop an allergic reaction or infection, including tetanus.

If you work near the ocean, you should be familiar with the marine life in your area.

YOU are the Provider SUMMARY

1. What are four factors that affect exposure?

Four factors that affect exposure are the physical condition of the patient, the patient's age, the patient's nutrition and hydration status, and environmental conditions. Patients who are already ill or in poor physical condition may not be able to tolerate extreme temperatures as well. Patients at extremes

of age (very young or older people) are more likely to experience illness as a result of temperatures. The body requires calories for metabolism, and malnourished or emaciated patients may not have the available calories to function. Finally, conditions such as air temperature, humidity, and wind can complicate environmental situations.

YOU are the Provider **SUMMARY** *continued***2. What are the five methods of heat loss?**

The five methods of heat loss are conduction, convection, evaporation, radiation, and respiration. Conduction occurs when heat passes from a warmer object to a cooler object. Convection occurs when heat is transferred to circulating air, such as across the body surface. Evaporation occurs when liquids convert to a gas. Radiation is the loss of body heat directly to colder objects in the environment by radiant energy, and respiration causes body heat to be lost because warm air in the lungs is exhaled and cooler air is inhaled.

3. Discuss ways to increase heat in the body.

The body can increase heat production by increasing the rate of metabolism of the cells. Actions a person can take to increase heat are to move to an area where heat loss is decreased, such as a warmer environment, and wear layers of clothing in cold environments.

4. What stage of hypothermia does this patient present in?

This patient is in severe hypothermia, evidenced by unresponsiveness, a weak and irregular pulse, and lack of shivering.

5. How can warmed, supplemental oxygen be provided to a hypothermic patient?

You can provide warmed, supplemental oxygen to a patient by applying hot packs to the oxygen tubing to warm the inspired oxygen that the patient receives.

6. What are some potential complications of rough handling of hypothermic patients?

The main complication of rough handling of patients experiencing a cold emergency is the possibility of inducing ventricular fibrillation because of the increased irritability of the hypothermic patient's heart. Rough handling can also result in increased pain and the potential for further injury.

7. What are the two methods of rewarming this patient?

The two methods for rewarming hypothermic patients are active and passive rewarming. Passive rewarming involves placing the patient in a warm environment, removing wet clothing, and applying heat packs or hot water bottles to the groin, axillary, and cervical regions. Active rewarming is best accomplished in the ED and includes therapies such as lavage with warm fluids and rewarming blood outside the body before reintroducing it (extracorporeal rewarming).

8. Why should active rewarming not be attempted in this patient?

When a patient has moderate or severe hypothermia, active rewarming is best accomplished in the ED. Rewarming the patient too quickly may cause a fatal dysrhythmia or other substantial complications. For this reason, local protocols may dictate the appropriate type of rewarming strategies based on the patient's body temperature.

Narrative

EMS dispatched to above location for unresponsive male. Temperature –20°F, heavy snow. On arrival, met by PD who states patient is a known transient who was probably trying to stay warm for the evening. Patient presents responsive to deep painful stimuli, breathing 14 breaths/min. Negative shivering. Rapid assessment of patient is unremarkable, with no obvious signs of trauma. Patient secured to stretcher, loaded into ambulance. All clothing removed, patient dried. Temperature in patient compartment placed at maximum, blankets applied to patient. 15 L/min of warmed supplemental oxygen given. Emergent transport initiated. 18-gauge IV established to left forearm with bolus of normal saline infusing. Active rewarming not initiated per protocols. On arrival at ED, care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- An environmental emergency is a medical condition caused or exacerbated by the weather, terrain, or atmospheric pressure at high altitude or underwater.
- Cold illness can be either a local or a systemic problem.
- There are four factors that affect how a person deals with a cold or hot environment: physical condition, age, nutrition and hydration status, and environmental conditions.
- The body's regulatory mechanisms normally maintain body temperature within a very narrow range around 98.6°F (37°C). Body temperature is regulated by heat loss to the atmosphere via conduction, convection, evaporation, radiation, and respiration.
- The key to treating hypothermic patients is to stabilize vital functions and prevent further heat loss. Do not attempt to rewarm patients who have moderate to severe hypothermia because they are susceptible to developing dysrhythmias.
- Do not consider a patient dead until the person is "warm and dead." Local protocol will dictate whether or not such patients receive CPR or defibrillation in the field.
- Local cold injuries include frostbite, frostnip, and immersion foot. Frostbite is the most serious because the tissues freeze. All patients with a local cold injury should be removed from the cold and protected from further exposure.
- If instructed to do so by medical control, rewarm frostbitten parts by immersing them in water at a temperature between 102°F and 104°F (38.9°C and 40°C).
- Heat illness can take three forms: heat cramps, heat exhaustion, and heatstroke.
 - Heat cramps are painful muscle spasms that occur with vigorous exercise. Treatment includes removing the patient from the heat, resting the affected muscles, and replacing lost fluids.
 - Heat exhaustion is essentially a form of hypovolemic shock caused by dehydration. Body temperature can be high, and the patient may or may not still be sweating. Treatment includes removing the patient

from the heat and treating for mild hypovolemic shock.

- Heatstroke is a life-threatening emergency, usually fatal if untreated. Patients with heatstroke are usually dry and will have high body temperatures. Often, the first sign of heatstroke is a change in behavior. Rapid lowering of the body temperature in the field is critical.
- Drowning is the process of experiencing respiratory impairment from submersion or immersion in liquid. Treatment for drowning begins with rescue and removal from the water. Immobilize and protect the patient's spine when a fall from a substantial height or suspected diving injury has occurred (or if this is a possibility). Be aware of the possibility of hypothermia.
- Diving emergencies during descent, at depth, and during ascent can occur as a result of the effects of changes in pressure. Organs in the body contain gases; the variation in the pressure of these gases with changes in atmospheric pressure and volume is described by Boyle's law, Dalton's law, and Henry's law.
- Diving emergencies include barotrauma, nitrogen narcosis, air embolism, and decompression sickness. Injuries associated with SCUBA diving may be immediately apparent or may show up hours later. Patients with air embolism or decompression sickness may have pain, paralysis, or altered mental status. Obtain a detailed diving history. Be prepared to transport such patients to a recompression facility with a hyperbaric chamber.
- High altitudes can cause dysbarism injuries, and include acute mountain sickness, high-altitude cerebral edema (HACE), and high-altitude pulmonary edema (HAPE). Field treatment includes providing oxygen, descending from the height, and transporting the patient.
- Lightning injuries may cause cardiac arrest and may damage the nervous system. Ensure the safety of the patient, yourself, and your partner. Look for an entrance and an exit wound. Use the concept of reverse triage when treating patients with lightning injuries. If CPR is instituted promptly, most lightning strike victims will survive.
- Venomous spiders include the black widow spider and the brown recluse spider; their bites are neurotoxic and cytotoxic, respectively, and can be life threatening.
- Anaphylactic reaction to Hymenoptera stings is a dire emergency and can be fatal if not recognized and treated quickly. Prompt removal of hymenopteran stingers or venom sacs can decrease toxin exposure.
- Venomous snakes include pit vipers (rattlesnakes, copperheads, and cottonmouths) and coral snakes.
- A person who has been bitten by a pit viper needs prompt transport; clean the bite area and keep the patient quiet to slow the spread of venom.
- If a patient has been bitten by a coral snake, notify the hospital as soon as possible. Coral snake venom can cause paralysis of the nervous system, and most hospitals do not have appropriate antivenin on hand.
- Scorpion stings can produce a severe systemic reaction. Antivenin is available but must be administered by a physician. If you suspect a scorpion sting, notify the receiving hospital as soon as possible.
- Patients who have been bitten by ticks may be infected with Rocky Mountain spotted fever or Lyme disease and should see a physician within a day or two. Remove the tick using tweezers, and save it for identification.
- Many marine envenomations may benefit from submersion in hot water to deactivate the heat-sensitive toxins. The patient still needs to be transported to the ED because the person could develop an allergic reaction or infection, including tetanus.
- Always provide prompt transport to the hospital for any patient who has been bitten by a venomous insect or animal. Remember that vital signs can deteriorate rapidly. Carefully monitor the patient's vital signs en route, especially for airway compromise.

Vital Vocabulary

air embolism The presence of air in the venous circulation, which forms a gas bubble that can block the outflow of blood from the right ventricle to the lung; can lead to cardiac arrest, shock, or other life-threatening complications.

ambient temperature The temperature of the surrounding environment.

antivenin A serum that counteracts the effect of venom from an animal or insect.

barotrauma Results from a pressure imbalance between gas-filled spaces inside the body and the external atmosphere.

bends Common name for decompression sickness.

breath-holding syncope Loss of consciousness caused by a decreased breathing stimulus.

conduction The loss of heat by direct contact (eg, when a body part comes in contact with a colder object).

convection The loss of body heat caused by air movement (eg, breeze blowing across the body).

core temperature The temperature of the central part of the body (eg, the heart, lungs, and vital organs).

decompression sickness A painful condition seen in divers who ascend too quickly, in which gas, especially nitrogen, forms bubbles in blood vessels and other tissues; also called the bends.

diving reflex Slowing of the heart rate caused by submersion in cold water.

drowning The process of experiencing respiratory impairment from submersion or immersion in liquid.

dysbarism injuries Any signs and symptoms caused by the difference between the surrounding atmospheric pressure and the total gas pressure in various tissues, fluids, and cavities of the body.

environmental emergency A medical condition caused or exacerbated by the weather, terrain, or by atmospheric pressure at high altitude or underwater.

evaporation Conversion of water or another fluid from a liquid to a gas.

frostbite Damage to tissues as the result of exposure to cold; frozen body parts.

frostnip A condition in which tissues have been exposed to dangerously cold elements but are still pliable; no permanent tissue damage occurs unless it escalates to frostbite; deeper tissues are unaffected.

heat cramps Painful muscle spasms usually associated with vigorous activity in a hot environment.

heat exhaustion A form of heat injury in which the body loses substantial amounts of fluid and electrolytes because of heavy sweating; also called heat prostration or heat collapse.

heatstroke A life-threatening condition of severe hyperthermia caused by exposure to excessive natural or artificial heat, marked by warm, dry skin; severely altered mental status; and often irreversible coma.

Hymenoptera A family of insects that includes bees, wasps, ants, and yellow jackets.

hyperbaric chamber A chamber, usually a small room, pressurized to a level higher than atmospheric pressure.

hyperthermia A condition in which the body core temperature rises to 101°F (38.3°C) or higher.

hypothermia A condition in which the body core temperature falls below 95°F (35°C) after exposure to a cold environment.

immersion foot A condition that occurs after prolonged exposure to cold water, in which the skin of the foot is pale and cold, and there is a loss of sensation; also called trench foot.

laryngospasm The spasmodic contraction of the vocal cords, accompanied by an enfolding of the arytenoid and aryepiglottic folds.

pulmonary overpressurization syndrome

(POPS) A diving emergency that can occur during rapid ascent and can cause pneumothorax, mediastinal and subcutaneous emphysema, alveolar hemorrhage, and the lethal air embolism; also called burst lung.

radiation The transfer of heat by radiant energy—for example, heat gain from a fire.

reverse triage A triage process in which efforts are focused on those who are in respiratory and cardiac arrest and different from conventional triage where such patients would be classified as deceased. Used in triaging multiple victims of a lightning strike.

SCUBA A system that delivers air to the mouth and lungs at various atmospheric pressures, increasing with the depth of the dive; stands for self-contained underwater breathing apparatus.

submersion Survival, at least temporarily, after suffocation in water or other liquids; also called near drowning.

thermogenesis The physiologic process of heat production in the body.

thermolysis The process of heat loss; methods include conduction, convection, radiation, evaporation, and respiration.

thermoregulation The balance between heat production and heat excretion.

turgor The ability of the skin to resist deformation; tested by gently pinching skin on the forehead or back of the hand.

wind-chill factor A measurement that takes into account the temperature and wind velocity in calculating the effect of a given ambient temperature on living organisms.

Chapter 35

Obstetrics and Neonatal Care

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Special Patient Populations

Applies a fundamental knowledge of growth, development, aging, and assessment findings to provide basic and selected advanced emergency care and transportation for a patient with special needs.

Obstetrics

- Recognition and management of
 - Normal delivery (p 1679)
 - Vaginal bleeding in the pregnant patient (pp 1663–1664, 1676–1678)
- Anatomy and physiology of normal pregnancy (pp 1658–1663)
- Pathophysiology of complications of pregnancy (pp 1663–1668)
- Assessment of the pregnant patient (pp 1672–1676)
- Management of
 - Normal delivery (pp 1679–1686)
 - Abnormal delivery (p 1686)
 - Nuchal cord (p 1691)
 - Prolapsed cord (pp 1691–1692)
 - Breech delivery (pp 1689–1690)
 - Third-trimester bleeding (pp 1677–1678)
 - Placenta previa (pp 1665–1666)
 - Abruptio placentae (p 1665)
 - Spontaneous abortion/miscarriage (pp 1676–1677)

- Ectopic pregnancy (p 1678)
- Preeclampsia/eclampsia (p 1678)

Neonatal Care

Assessment and management

- Newborn (pp 1672–1676, 1681–1684, 1686–1687)
- Neonatal resuscitation (pp 1693–1703)

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Special Considerations in Trauma

Recognition and management of trauma in

- Pregnant patient (p 1670)
- Pediatric patient (Chapter 36, *Pediatric Emergencies*)
- Geriatric patient (Chapter 37, *Geriatric Emergencies*)

Pathophysiology, assessment, and management of trauma in the

- Pregnant patient (pp 1670–1676)
- Pediatric patient (Chapter 36, *Pediatric Emergencies*)
- Geriatric patient (Chapter 37, *Geriatric Emergencies*)
- Cognitively impaired patient (Chapter 38, *Patients With Special Challenges*)

KNOWLEDGE OBJECTIVES

1. Review the anatomy and physiology of the female reproductive system and gestation. (pp 1658–1661)
2. Describe the normal changes that occur in the body during pregnancy. (pp 1661–1663)
3. Discuss the pathophysiology of conditions affecting pregnancy, including spontaneous abortion (miscarriage), ectopic pregnancy, hypertension, substance abuse isoimmunization, gestational diabetes, placenta previa, abruptio placentae, trauma, and physical abuse. (pp 1663–1668)
4. Recognize the need to consider two patients—the woman and the unborn fetus—when treating a pregnant trauma patient. (pp 1668–1669)
5. List special considerations involving pregnancy in different cultures and with teenage patients. (pp 1671–1672)
6. Describe commonly used obstetric terminology. (p 1672)
7. Outline the assessment process for pregnant patients. (pp 1670–1671)
8. Describe the indications of an imminent delivery. (pp 1672–1673)
9. Discuss assessment and management of nondelivery emergencies. (pp 1676–1679)
10. Differentiate between the three stages of labor. (p 1679)
11. Explain the steps involved in normal delivery management. (pp 1679–1681)
12. Explain the necessary care of the baby as the head appears. (pp 1681–1684)
13. Discuss Apgar scores, including how and when to obtain them. (p 1684)
14. Describe the procedure followed to cut and tie the umbilical cord. (p 1684)
15. Describe delivery of the placenta. (pp 1684–1685)
16. Discuss postpartum care to provide, including addressing postpartum hemorrhage. (pp 1685–1686)
17. Explain how to manage complications of labor, including preterm labor, postterm pregnancy, fetal distress, and uterine rupture. (pp 1686–1688)
18. Discuss high-risk pregnancy conditions and their prehospital management, including meconium staining, multiple gestation, cephalopelvic disproportion, intrauterine fetal death, and amniotic fluid embolism. (pp 1688–1689)
19. Discuss complications of delivery, including breech presentation, limb presentation, shoulder dystocia, nuchal cord, and prolapsed umbilical cord. (pp 1689–1692)
20. Discuss postpartum complications and their prehospital management, including excessive bleeding, uterine inversion, pulmonary embolism, and spina bifida. (pp 1692–1693)
21. Discuss the initial steps of assessment for neonates, including drying and warming, positioning, suctioning, and stimulation. (pp 1695–1697)
22. Explain how to measure essential parameters including heart rate, color, and respiratory effort. (pp 1697–1698)
23. List the steps of the algorithm for neonatal resuscitation, including key time frames for interventions. (pp 1697–1699)
24. Discuss techniques for airway management during neonatal resuscitation. (pp 1699–1701)
25. Discuss techniques for circulation support during neonatal resuscitation. (pp 1701–1703)
26. Describe vascular access considerations in the neonate. (pp 1701–1703)
27. Discuss assessment and management of specific emergencies including apnea or inadequate respiratory effort, bradycardia, hypoglycemia, and hypovolemia. (pp 1703–1705)

SKILLS OBJECTIVES

1. Demonstrate the procedure to assist in a normal cephalic delivery. (pp 1682–1683, Skill Drill 35-1)
2. Demonstrate care procedures of the infant as the head appears. (pp 1681–1684)
3. Demonstrate the steps to follow in postdelivery care of the infant. (p 1684)
4. Demonstrate how to cut and tie the umbilical cord. (p 1699)
5. Demonstrate how to assist in delivery of the placenta. (p 1665)
6. Demonstrate the postdelivery care of the woman. (p 1685)
7. Describe how to assist with a breech delivery in the field. (p 1690)
8. Describe how to assist with a limb presentation in the field. (p 1690)
9. List the steps of neonatal resuscitation. (p 1698)
10. Explain how to perform chest compressions on a neonate. (pp 1701–1702)

Introduction

Most births are uneventful and require little or no medical intervention beyond basic interventions, such as suctioning, drying, and warming the baby; others, however, may be life threatening to both the woman and baby. Arriving at the scene of a woman in labor can cause anxiety and fear on the part of both the advanced emergency medical technician (AEMT) and the expecting parents. Parents usually expect to deliver their child in the controlled setting of a hospital delivery room. Unfortunately, if labor progresses quickly or other factors intervene, you may have to deliver the newborn in the field. The birthing process usually requires little help from the health care provider, only supportive care of the pregnant woman and newborn.

This chapter will describe and discuss the normal anatomic and physiologic changes that occur during pregnancy, the normal process of childbirth, and common complications. You will learn how to assess whether to proceed with delivery in the field, how to deliver a newborn, how to manage delivery complications, and how to perform neonatal resuscitation.

Anatomy and Physiology Review: The Female Reproductive System

The female reproductive system includes the ovaries, fallopian tubes, uterus, cervix, vagina, and

breasts. Hormones from the pituitary gland stimulate the **ovaries** to produce oocytes, which undergo oogenesis that results in an **ovum**, or mature egg cell. An ovum is released regularly, approximately every 28 days, during the adult female's reproductive years. This egg travels through the **fallopian tubes**, hollow tubes or ducts that extend from the uterus to the region of the ovary, where fertilization normally occurs. The fallopian tubes exit into the **uterus**. For more on the female reproductive system, see Chapter 7, *The Human Body*.

During each menstrual cycle, the lining of the uterus thickens in preparation for pregnancy. Pregnancy most frequently occurs during a certain time in the menstrual cycle, after an ovum is mature. If fertilization occurs, the fertilized ovum proceeds through the fallopian tube to implant in the uterus. If fertilization does not occur, the lining of the uterus sheds during **menstruation**.

The **vagina** is the female organ that receives the male penis during sexual intercourse. The muscular walls of the vagina are able to expand, allowing the vagina to stretch greatly during childbirth.

The female external genitalia include the vulva, the labia minora, the clitoris, the prepuce, the labia majora, and the mons pubis. The **perineum** is the area between the urethral opening and the anus. It includes skin, the external genitalia, and underlying tissues.

FIGURE 35-1 shows the anatomic structures of the pregnant female. The top portion of the uterus is called the **fundus**, and the main portion of the

YOU are the Provider

Part 1

You and your partner are dispatched to intercept with a vehicle, southbound on I-75 at mile marker 135, for a woman in labor. After you intercept with the vehicle, you find the patient in the rear of the vehicle in obvious distress. She states that they were on their way to the hospital but her contractions keep getting closer together and stronger, and she thought it best to call for an ambulance. The patient states that this is her second pregnancy and that her first baby was born at 29 weeks' gestation. She also tells you that she has a medical history of eclampsia and gestational diabetes.

You decide that the patient needs to be transported via ambulance. Your partner brings the stretcher alongside the car and you assist her onto it and load her into the ambulance. After the patient is placed inside of the ambulance, she tells you she feels a lot of pressure "down there." You turn the heat all the way up and instruct the patient to remove her undershorts. On physical exam, you do not note any crowning or discharge.

1. What stage of labor is the patient in?
2. Is this patient's medical history important?

uterus is the body. The **cervix** is the part of the uterus that extends into the vagina. The vagina and cervix together are referred to as the **birth canal**.

Gestation

Gestation refers to the process of fetal development following fertilization of an egg. Fertilization occurs when sperm and an ovum meet, usually in the distal third of the fallopian tube. The fertilized egg, called the **zygote**, moves through the fallopian tube toward the uterus. At the same time, the

zygote undergoes progressive cell divisions. When the **embryo** contains approximately 32 cells, it usually implants into the uterine wall, which has been thickened by progesterone in preparation for implantation. Implantation usually occurs approximately 7 days after fertilization. The inner group of blastocyst cells (the embryoblast) becomes the embryo; the outer group of cells (the trophoblast) becomes the **placenta** (FIGURE 35-2). From the time of fertilization to the end of the ninth week, the developing embryoblast part of the blastocyst is referred to as an embryo; in the 10th week and beyond, it is referred to as a **fetus**. Approximately 3 weeks after fertilization, the placenta is formed in the uterus and merges the fetal and maternal tissue to provide nutrients to and eliminate waste products from the developing fetus.

Around the fourth week of pregnancy, the placenta begins to develop. Essentially an enlarged endocrine gland, the placenta carries out several crucial functions during pregnancy. It serves as an early liver for the developing fetus, taking care of the synthesis of glycogen and cholesterol, metabolizes fatty acid, and allows for the transfer of certain antibodies that protect the fetus. The placenta also provides the following functions:

- **Respiratory gas exchange.** The placenta functions as the fetal lungs, enabling the fetus to exchange its carbon dioxide-laden blood for oxygen-rich blood.

FIGURE 35-1 Anatomic structures of the pregnant female.

© Jones & Bartlett Learning.

FIGURE 35-2 Fertilization and implantation of the embryo.

© Jones & Bartlett Learning.

- Transport of nutrients from maternal to fetal circulation.
- Excretion of wastes, some of which pass into the maternal circulation and others of which are excreted into the amniotic fluid.
- Transfer of heat from the woman to the fetus.
- Hormone production. About 10 to 12 weeks after conception, the placenta is sufficiently developed to assume responsibility for the production of human chorionic gonadotropin (hCG), a hormone that maintains the pregnancy and stimulates changes in the woman's breasts, vagina, and cervix that prepare her for delivery and motherhood.
- Formation of a barrier against harmful substances in the pregnant woman's circulation, such as chemicals or microorganisms. When the placenta blocks a drug from reaching the fetal bloodstream, it means the drug "does not cross the placenta." The placenta is not able to exclude every harmful substance from reaching the fetus; however, so you need to be very careful when administering medications to women during pregnancy.

The **umbilical cord** connects the placenta to the fetus via the fetal umbilicus (navel). The cord is gray, easily compressed, and soft and pliant though structurally tough. The umbilical cord contains two arteries and one vein.

Fetal circulation differs from that of the pregnant woman. The umbilical vein carries oxygenated blood from the placenta to the fetus, while the umbilical arteries carry deoxygenated, nutrient-depleted blood from the fetus to the placenta. Because the fetus obtains its oxygen via the placenta, the fetal circulation bypasses the lungs until birth. A duct connects the umbilical vein and the inferior vena cava (the ductus venosus), another duct connects the pulmonary artery and the aorta (the **ductus arteriosus**), and the septum separates

the right and left atria of the fetal heart. During gestation, an opening between the right and left atria (the **foramen ovale**) allows oxygen-rich blood to travel from the right atrium to the left atrium and then to the left ventricle and out the aorta, ensuring the blood with the most oxygen reaches the brain. At birth, the neonate's lungs begin to function, and these arteriovenous shunts close.

The **amniotic sac** (also called the amniotic membranes) is a membranous bag that fills with **amniotic fluid** to protect and cushion the developing fetus. The amniotic fluid is produced by the filtration of maternal and fetal blood through blood vessels in the placenta and by excretion of fetal urine into the amniotic sac. Amniotic fluid is swallowed by the fetus and removed by the placenta, where it passes into the woman's blood. The amount of amniotic fluid reaches about 500 to 1,000 mL (1 L) at term, but this volume is constantly changing throughout the pregnancy and reduces to one-half liter by the time the fetus is at term. During labor, when the fetus descends into the birth canal, the pressure on the amniotic sac causes its rupture (**rupture of membranes**). This rupture releases the amniotic fluid that has cushioned the fetus during development. If the amniotic sac ruptures before labor occurs, the fetus is at higher risk for complications, including trauma and infection. This is called **premature rupture of membranes**.

The **gestational period** is the time that it takes for the infant to develop in utero. This process normally takes 38 weeks, with substantial developmental progress occurring each week except for the last several weeks, in which growth primarily occurs. The time of conception is calculated from the first day of the pregnant woman's last menstrual period. This dating method adds 2 weeks to the entire calculation, resulting in a standard 40 total weeks of pregnancy from conception to birth. Some normal pregnancies may last more than 40 weeks.

These 40 weeks of pregnancy form the prenatal period and are divided into three **trimesters** (**FIGURE 35-3**). The first trimester extends from the last menstrual cycle through week 12 of the pregnancy. Major events in the first trimester include a positive pregnancy test result (blood or urine hCG) at 8 to 10 days, a palpable uterine fundus at the pubic symphysis at week 12, and audible fetal heart tones noted on Doppler ultrasonography. All major fetal organ systems begin to develop

Words of Wisdom

Remember: Arteries always carry blood away from the heart, and veins always carry blood toward the heart. Therefore, the umbilical arteries carry deoxygenated blood away from the heart (to the placenta). Oxygenated blood is returned to the fetus's heart via the umbilical vein.

FIGURE 35-3 The three trimesters of pregnancy. You will usually not be able to see any physical change in a woman during the first trimester. You may be able to estimate whether the woman is in the second or third trimester.

© Jones & Bartlett Learning.

during the **embryonic period** (weeks 3 through 8) (**FIGURE 35-4**). From the embryonic period until delivery, organ systems undergo continuing maturation and development.

The second trimester extends from week 13 through week 27. The major events are a palpable uterine fundus between the pubic symphysis and the umbilicus at week 16, the first fetal movements (quickening) at weeks 16 through 18 in a woman who has had one or more previous pregnancies, and fetal heart tones that become audible with a **fetoscope** at weeks 17 through 20. In addition, female and male genitalia may be distinguished by **ultrasonography** at week 18, first fetal movements are noted in a woman's first pregnancy at weeks 18 through 20, and the uterine fundus is palpable at the umbilicus at week 20. At weeks 25 through 27, the lungs become capable of respiration and produce surfactant, a liquid protein substance that coats the alveoli in the lungs.

The third trimester extends from week 28 until **term** (week 40). The major events of the third

FIGURE 35-4 All major organ systems begin to develop during the embryonic period.

© Claude Cortier/Science Source.

trimester include the presence of papillary light reflex in the fetus, descent of the fetal head to the pelvic inlet (lightening), and rupture of the amniotic sac. After the amniotic sac has ruptured, it is optimal that the fetus be delivered within 24 hours because of the risk of infection. At the end of the third trimester, the fetus typically weighs 7.0 to 7.5 lb (approximately 3.2 to 3.4 kg).

A **newborn** is a recently born baby and is generally considered “newborn” for the first few hours of its life. During the first 28 days of life, a baby is considered to be a **neonate**. Between the ages of 1 month and 1 year, a baby is referred to as an **infant**.

Special Populations

A newborn delivered at less than 37 completed weeks of gestation is considered **preterm**; a newborn born at 38 to 42 weeks of gestation is described as term; and a newborn born at 42 weeks or more of gestation is described as postterm (or postdates).

Normal Maternal Changes of Pregnancy

In addition to changes in the reproductive system, during pregnancy, many other body systems undergo changes to support the growing fetus.

The maternal cardiovascular system undergoes dramatic changes during pregnancy. The total blood volume increases by about 50% by 40 weeks and the red blood cells increase in number by about 30%. The heart rate elevates by 10 to 20 beats/min. Cardiac output increases by 30% to 50% more than the prepregnancy level, reaching its maximum capacity at approximately 22 weeks' gestation, and then declines to approximately 20% near term.¹ The systolic and diastolic blood pressures decrease by 10 to 15 mm Hg by the second trimester of pregnancy and return to near-normal by full term. In the second and third trimesters of pregnancy, the **gravid** (pregnant) uterus may compress the woman's inferior vena cava when she lies supine. This can substantially reduce the return of blood to the heart (preload), thereby causing a decrease in blood pressure.

The increase in red blood cells heightens the pregnant woman's need for iron, which is why most women have to take prenatal vitamins. If the woman does not take iron supplements, the fetus will rob maternal stores for its needs, resulting in anemia for the woman and possibly resulting in preterm labor or **spontaneous abortion** (miscarriage). Women who live in socioeconomically disadvantaged areas and lack access to prenatal health care, along with those who do not obtain prenatal health care, are

the most likely to experience pregnancy-related anemia.

The respiratory minute volume of the patient increases by about 40% by full term to accommodate the increased blood volume and demand for oxygen from the fetus. In pregnancy, the woman's tidal volume also initially increases. After the gravid uterus has grown enough to lie against the diaphragm, the patient may not be able to fully inspire the tidal volume needed to maintain adequate minute volume. If so, the woman's respiratory rate increases to compensate for the reduced tidal volume.

Because of the increase in the amount of air that goes in and out of the lungs, the amount of carbon dioxide that the patient exhales increases. A relative respiratory alkalosis develops in the patient, which may cause dizziness and shortness of breath. Also, carbon dioxide produced by the fetus travels to the placenta and diffuses into the maternal bloodstream.

The pregnant woman often experiences gastrointestinal complaints at some time during the pregnancy. Often called morning sickness, nausea and sometimes vomiting occurs most commonly between the 8th and 14th week of pregnancy. As the uterus grows later in the pregnancy, the stomach and intestines of the woman are compressed and pushed superiorly, resulting in heartburn, a

YOU are the Provider

Part 2

The patient states that she is approximately 32 weeks pregnant based on her last menstrual cycle and has not had any prenatal care. You note that her contractions are approximately 1 minute in length and 1 minute apart. You obtain a set of vital signs as your partner prepares the obstetric (OB) kit. As a precaution, you establish an 18-gauge intravenous (IV) line in her right forearm with normal saline solution at a to-keep-open (TKO) rate. Just as you finish securing the IV site, the patient states that she needs to have a bowel movement "NOW!"

Recording Time: 1 Minute

Appearance	Anxious
Level of consciousness	Alert and oriented to person, place, day, and event

Circulation	Strong radial pulses; skin warm and dry

- Is immediate transport of this patient warranted?
- Does this patient need IV access at this point?

burning sensation around the epigastrium. If the patient is unresponsive and has no gag reflex, the risk of regurgitation and aspiration also increases. The peristalsis of the bowels decreases from the pressure of the uterus on the gastrointestinal tract and so digestion slows, often resulting in constipation. Decreased gastrointestinal function could also affect the absorption of medications, resulting in medications remaining in the blood longer than usual.

On average, the pregnant woman gains approximately 27 lb (12 kg) during a full-term pregnancy. If the patient gains substantially more weight than average, she may be at risk for several of the disorders of pregnancy that will be discussed later. Pregnant women often have edema in their lower extremities.

All of these are monitored with standard prenatal care. If the woman has not received prenatal care, the potential for complications can be increased.

Pathophysiology During Pregnancy

Many complications can occur during the pregnancy that can threaten the health or life of both the woman and fetus. We will examine the most common of these conditions. One of the common early pregnancy emergencies that you will care for is vaginal bleeding. This can be a sign of several conditions that range from benign to life threatening.

Abortion

The most common cause of vaginal bleeding during the first and second trimesters of pregnancy is spontaneous abortion or miscarriage. Most spontaneous abortions occur during the first trimester, before the placenta is fully mature. The term *abortion* does not imply any cause and simply means that the fetus is released from the uterus before 20 weeks of gestation (**FIGURE 35-5**).

Abortions can be broadly classified as spontaneous or elective (induced). A spontaneous abortion (miscarriage) occurs naturally, and affects an estimated 10% to 25% of all pregnancies.² Causes may include acute or chronic illness in the pregnant woman, maternal exposure to toxic substances (illicit drugs), abnormalities in the fetus, or abnormal attachment of the placenta. In many cases,

FIGURE 35-5 A miscarried fetus.

Courtesy of Rhonda Hunt.

the cause of a spontaneous abortion cannot be identified.

An **elective abortion** is brought about intentionally. When you are obtaining a medical history that includes an abortion, you must be dispassionate and professional regardless of your personal convictions. You may encounter patients who are experiencing complications following an elective abortion, such as vaginal bleeding or sepsis from having parts of the fetus remaining in the uterus. You may also encounter patients who have “self-medicated” in an attempt to induce an abortion and are experiencing toxic effects of the herbal remedy as well as a threatened or progressing abortion. Herbal preparations work by making the uterus and bloodstream too toxic for the fetus to survive, which may be too toxic for the woman to survive.

A **threatened abortion** is an abortion that is impending or potentially occurring. It is generally characterized by vaginal bleeding during the first half of pregnancy, usually in the first trimester. The patient may present with abdominal discomfort or report menstrual cramps. Severe pain is rarely a presenting complaint because uterine contractions are not rhythmic. The cervix remains closed. A threatened abortion can progress to a miscarriage or abortion, or it may subside, allowing the pregnancy to go to term. The treatment for a threatened abortion is usually complete bed rest to avoid activity or fluctuations in vital signs that could further provoke an abortion. Your role in this case is usually transport and emotional support.

An **imminent abortion** is an impending or threatened spontaneous abortion that cannot be prevented. The patient will generally present with severe abdominal pain caused by strong uterine contractions. Vaginal bleeding, sometimes substantial, will be present, as well as cervical dilation because the uterus is preparing to expel the products of conception. When you are treating a patient who is experiencing a spontaneous abortion, your goals are to maintain blood pressure and prevent hypovolemia. Treatment consists of administering 250-mL boluses of normal saline, repeating as needed, to maintain a systolic blood pressure of greater than 80 mm Hg; 100% supplemental to maintain an SpO₂ level of greater than 94%; and providing emotional support with rapid transport. Be alert for signs of shock.

An **incomplete abortion** occurs when part of the products of conception are expelled but some remain in the uterus. (For example, the fetus is expelled but the placenta remains, or only part of the fetus is expelled.) Because the cervix has dilated to expel the fetus, vaginal bleeding will be present, which may be slight or substantial, but will be continuous. Be alert for signs and symptoms of shock, and start an IV line of normal saline. If products of conception are protruding from the vagina, consult medical control for instructions; gentle removal of protruding tissues may prevent or relieve signs of shock. You will most often encounter this situation when you find the patient on the toilet, having attempted a bowel movement, with the fetus in the toilet still attached to the umbilical cord hanging from the vagina. The fetus should be gently collected, and emotional support provided to the patient. Fundal massage may be beneficial in stimulating the placenta to deliver. All products of conception need to be collected and presented to the receiving facility. Do not deter the patient from viewing the fetus if she wishes, but be prepared for a strong emotional reaction. A **complete abortion** has occurred when all the products of conception have been expelled.

Ectopic Pregnancy

Another cause of first-trimester bleeding is the implantation and growth of the embryo outside of the uterus. This **ectopic pregnancy** can implant in the fallopian tube, on the ovary, in the abdominal

cavity or peritoneum, or in the cervix. The most common place to find an ectopic pregnancy is in the fallopian tube (tubal pregnancy). During the first trimester, the embryo grows rapidly. It quickly grows into the walls of the fallopian tube, where it causes tearing and finally ruptures the tube. As this occurs, the woman usually feels lower abdominal pain and cramping. She usually, but not always, has vaginal bleeding. Depending on where the embryo implants, the bleeding may be internal or external and may be scant or profuse. This can be a life-threatening emergency for the pregnant woman during the first trimester. The embryo will not survive and must be removed surgically to save the woman. If the fallopian tube ruptures, she may present to you in severe shock and possibly cardiac arrest from massive hemorrhage. Ectopic pregnancy is discussed in Chapter 25, *Gynecologic Emergencies*.

Third-Trimester Bleeding

Abortion accounts for most vaginal bleeding that results in an emergency call. Any detachment of the ovum or embryo from the uterine wall will result in bleeding. The patient may report light or heavy bleeding, normally accompanied by cramping abdominal pain. She may also report the passage of tissue or clots. Vaginal bleeding is a serious sign at any stage of pregnancy, but the complications of bleeding increase as the gestation progresses.

Third-trimester bleeding presents the most dangerous hemorrhage in terms of risk to the health of the mother. This becomes even more acute as the woman approaches term. A complicating factor

Words of Wisdom

Any bleeding from the vagina in a pregnant woman is a serious sign and should be treated promptly in the hospital. If the patient shows signs of shock, position her on her left side, administer high-flow oxygen, keep her warm, and provide rapid transport. Gain IV access and give 250-mL boluses of an isotonic crystalloid to maintain perfusion as needed. Place a sterile or sanitary pad over the vagina, replacing it when soaked. Keep all pads, and any tissue that may be passed from the vagina, for examination at the hospital. Never place anything inside the vagina to control bleeding.

of third-trimester bleeding is the large volume of blood present within the pregnant woman's body and the compensatory mechanisms that are functioning as a result of pregnancy. A pregnant woman can lose a full 40% of her circulating volume before substantial signs and symptoms of hypovolemia become apparent.

Bleeding and the Placenta

Major causes of substantial hemorrhage before delivery are abruptio placentae and placenta previa.

Abruptio placentae refers to a premature separation of a normally implanted placenta from the wall of the uterus (**FIGURE 35-6**). It most commonly occurs during the last trimester of pregnancy, but can take place in the second trimester as well. Abruptio placentae affects approximately 1 of every 100 pregnancies that go to term.^{3,4} Although the exact cause of abruptio placentae is unknown, hypertension, trauma, drug use, alcohol use, diabetes, and having multiple pregnancies increase the risk for this condition.^{3,4}

The patient with abruptio placentae will present with a sudden onset of severe abdominal pain, often radiating into the back; there will also be decreased fetal movement and decreased fetal heart tones. The patient may report vaginal bleeding, although in some cases the blood does not

emerge through the cervix and the bleeding may remain concealed within the endometrium. Physical examination may reveal signs of shock, often out of proportion to the apparent volume of blood loss. The abdomen will be tender and the uterus rigid to palpation. Other complications include severe hemorrhaging. If the hemorrhaging cannot be controlled after delivery, a hysterectomy may be necessary.

In **placenta previa**, the placenta is implanted low in the uterus and, as it grows, it partially or fully obscures the cervical canal (**FIGURE 35-7**). This condition is the leading cause of vaginal bleeding in the second and third trimesters of pregnancy, with most problems occurring near term because the cervix begins to dilate in preparation for delivery. Maternal age and multiparity are risk factors. Placenta previa occurs in approximately 1 of every 200 pregnancies,⁵ with a maternal mortality rate of less than 1%.⁶ Complications may include disseminated intravascular coagulation, hemorrhage, and low fetal birth weight.

The chief complaint of a woman with placenta previa is usually painless vaginal bleeding, with the expulsion of bright red blood from the vagina. Because the blood supply to the fetus is not immediately jeopardized, fetal movements continue and fetal heart sounds remain audible. On gentle palpation, the uterus is soft and nontender. (Do *not*

FIGURE 35-6 In abruptio placentae, the placenta separates prematurely from the wall of the uterus.

try to palpate the abdomen deeply in any woman with third-trimester bleeding; if she does have placenta previa, deep palpation may induce heavy bleeding.)

Hypertensive Disorders

Hypertension is a major cause of mortality and morbidity in the pregnant woman. During pregnancy, blood pressure is usually lower than at pre-pregnancy levels, but women who are hypertensive or borderline hypertensive may have their hypertension exacerbated by pregnancy.

Chronic hypertension is defined as a blood pressure that is equal to or greater than 130/80 mm Hg, which existed prior to pregnancy, occurs before the 20th week of pregnancy, or continues to persist postpartum.⁷ Diastolic pressures higher than 110 mm Hg place the patient at an increased risk for stroke and other cardiovascular dangers. Chronic hypertension can also retard growth and development of the fetus, impair liver and renal function, cause pulmonary edema, or progress to life-threatening tonic-clonic seizures.

Gestational hypertension (formerly known as pregnancy-induced hypertension) develops after the 20th week of pregnancy in women with previously normal blood pressures and resolves spontaneously in the postpartum period. It is more commonly experienced by women who are obese or glucose intolerant.

Preeclampsia is defined as an increase in blood pressure after the 20th week of gestation. Women younger than 18 years who are experiencing their first pregnancy, women with advanced maternal age (those who are 35 years or older), and women with risk factors of chronic hypertension, renal disease, and diabetes are all at increased risk for preeclampsia.⁸ In the first trimester of pregnancy the blood pressure typically increases slightly; it decreases below the baseline during the second trimester and returns to the baseline during the third trimester. Chronic hypertension can retard growth and development of the fetus; in the woman, it can impair liver and renal function, cause pulmonary edema, or progress to life-threatening tonic-clonic seizures.

Preeclampsia is accompanied by a protein release in the urine and often by edema, particularly in the face, ankles, and hands. The protein in the urine will not typically be detected by emergency

medical services (EMS) personnel, and edema can be normal for a pregnant woman.

The most important feature of preeclampsia for you to recognize is hypertension. Other symptoms include severe headache, nausea and vomiting, agitation, rapid weight gain, and visual disturbances.

Words of Wisdom

Preeclampsia manifests after the 20th week of pregnancy, with the onset of a triad of symptoms: edema, usually of the face, ankles, and hands; gradual onset of hypertension; and protein in the urine.

Eclampsia is a seizure in a pregnant woman who has preeclampsia and no other cause for the seizure. A woman who is an epileptic and has a seizure may or may not be eclamptic. Eclampsia may occur before labor, during labor, after delivery of the newborn, or even up to several weeks following delivery (postpartum eclampsia). A woman may have only one seizure or may have continuous or multiple seizures (status epilepticus). **Postpartum eclampsia** usually presents within the first 24 hours after delivery, but may occur as late as 4 weeks following the birth. Chapter 25, *Gynecologic Emergencies*, discusses eclampsia and related seizures in more detail.

Another common finding in a pregnant patient is hypotension when lying supine, called **supine hypotensive syndrome** or inferior vena cava compression syndrome, which may be an issue when a woman is injured and must be immobilized. This happens mainly in the second and third trimesters of pregnancy when the woman lies supine (but can occur when sitting) and is a result of compression of the inferior vena cava by the weight of the gravid uterus.⁹ Left uncorrected, supine hypotensive syndrome can result in substantial maternal hypotension and potentially result in fetal distress because the maternal hypotension translates into placental hypoperfusion. It generally takes 3 to 7 minutes of compression before signs and symptoms manifest, and in most women, symptoms never develop. Nausea, dizziness, tachycardia, and claustrophobia are early signs, progressing to breathing difficulty and syncopal episodes. Precipitating factors may include hypovolemia, from either blood loss or dehydration.

Words of Wisdom

Simply rolling the patient onto the left side alleviates supine hypotension. If the patient is on a long backboard, tilt the board approximately 30° to the left by propping it up, for example, with blankets.

Effects of Substance Abuse

When a pregnant woman inappropriately uses drugs, the substances pass through the placental barrier and enter the fetal circulation. Birth defects may then develop and the fetus may become addicted. The effects of the substance on the fetus can include prematurity, low birth weight, and severe respiratory depression. In addition, these women often have received little or no prenatal care. When delivering the fetus of a woman with a history of drug abuse, be aware that the newborn may have signs of withdrawal, such as respiratory depression, bradycardia, tachycardia, seizures, or cardiac arrest. Treatment should revolve around cardiorespiratory support.

Fetal alcohol syndrome (FAS) is a condition seen in infants born to women who have abused alcohol. According to the Centers for Disease Control and Prevention (CDC), studies show that there are 0.2 to 1.5 infants with FAS for every 1,000 live births in some areas of the United States.¹⁰ The most extreme form of FAS results in fetal death due to harm to the developing fetus from maternal alcohol consumption.¹¹ Alcohol abuse appears to be most harmful during the first trimester. Physical characteristics of newborns with FAS may include a small head, abnormal facial features (including small and wideset eyes, thin upper lips, short upturned noses, and/or smooth skin between the upper lip and nose), low birth weight, and deformities of extremities. Prehospital treatment is supportive. Maintain ABCs (airway, breathing, and circulation) and pay particular attention to keeping the newborn warm.

Isoimmunization (Rh Sensitization)

Rh factor is a protein found on the red blood cells of most people. When the factor is absent, the person

is said to be Rh negative. When a woman who is Rh negative becomes pregnant by a man who has the Rh factor (Rh positive) and the fetus inherits this factor, the fetal blood can pass into the woman's circulation and produce maternal antibody (isoimmunization) to the factor. See Chapter 7, *The Human Body*, for more information.

This is normally not a problem in first pregnancies, but in subsequent pregnancies, the antibody will aggressively cross the placental barrier to attack the fetal red blood cells, which the woman's body identifies as foreign proteins. This attack can result in death for the fetus or cause hemolytic disease (erythroblastosis fetalis) in a newborn. Newborns with hemolytic disease may present with jaundice, anemia, and hepatomegaly.

Gestational Diabetes

Gestational diabetes mellitus is the inability to process carbohydrates during pregnancy. Increased maternal insulin production may lead to an imbalance between the supply of the woman's insulin and glucose production. The patient may be asymptomatic or may exhibit the same signs observed in patients with diabetes mellitus: polyuria, polydipsia, and polyphagia. As gestational diabetes mellitus may occur early in the pregnancy, it is recommended that patients undergo a fasting glucose test as part of routine prenatal testing.

Diabetes may be markedly affected by pregnancy. As the hormones of pregnancy alter the insulin-regulating mechanisms, patients with diabetes may experience wildly fluctuating blood glucose levels, manifested as hyperglycemic or hypoglycemic episodes. Unfortunately, oral hypoglycemic agents can cross the placental barrier and affect the fetus, so treatment for women with new-onset gestational diabetes is limited to meal planning, blood glucose testing, and possibly insulin use.

Gestational diabetes predisposes the patient to hyperglycemia or hypoglycemia. If a woman with preexisting or gestational diabetes does not control her blood glucose levels throughout her pregnancy, she may have problems during labor and delivery. The fetus may grow to a larger-than-average size and may not fit through the birth canal. Additionally, diabetes (gestational diabetes or diabetes mellitus) in a pregnant woman predisposes the

newborn to hypoglycemia. Usually, gestational diabetes spontaneously resolves following delivery.

Hyperemesis Gravidarum

Nearly all women experience the infamous (but normal) “morning sickness,” especially during the first several weeks of pregnancy. **Hyperemesis gravidarum** is a condition of persistent nausea and vomiting during pregnancy.¹² Its prolonged vomiting results in dehydration and malnutrition, which have negative effects on the woman and fetus. The exact cause of the condition is unknown, but suspected causes include increased hormone levels (especially estrogen and human chorionic gonadotropin), stress, and changes to the gastrointestinal system. Hyperemesis gravidarum is most common in first-time pregnancies, with multiple gestations, and in women who are obese. Symptoms include severe and persistent vomiting, in excess of three or four times daily. Vomiting is usually projectile and generally consists of bile and possibly blood. Severe nausea, pallor, and possibly jaundice may also be seen.

Prehospital treatment includes administering 100% oxygen via nonrebreathing mask, checking blood glucose level, providing an IV line of normal saline with fluid boluses as needed, and providing transport. Severe cases require hospitalization.

Special Populations

Any pregnant patient with a history of hyperemesis gravidarum who presents with hematemesis should alert you to the possibility of a Mallory-Weiss tear. This typically occurs after a prolonged or forceful bout of straining or vomiting and hyperemesis gravidarum is the most common cause in women of childbearing age.¹³ Maintain the airway and provide rapid transport. Gain IV access en route.

Premature Rupture of Membranes

When the amniotic sac ruptures or “opens” more than 1 hour before labor, it is called premature rupture of the membranes. In some instances, the sac will self-seal and heal itself, but more commonly, labor will begin within 48 hours. If the pregnancy is at or near term, there is usually no concern. However, if the pregnancy is not yet at term, there is a risk of

infection. In either situation, you should provide emotional support to the patient and provide transport to the hospital.

Effects of Physical Abuse

Intimate partner violence often begins or worsens during pregnancy. Abuse during pregnancy increases the risk of spontaneous abortion, premature delivery, and low birth weight. The woman is at risk of bleeding, infection, and uterine rupture. Pay particular attention to the environment for signs of abuse. Attention to detail will be helpful in your documentation and in informing physicians and hospital staff who may care for the patient.

Pregnant patients who are abused may be reluctant to explain how their injuries occurred. Suspect abuse when the story of how an injury happened does not make sense. Try to talk with the patient in private and provide reassurance. The best way to care for the fetus is to provide excellent care for the mother. Support the patient’s ABCs, control any bleeding, stabilize extremity injuries, and treat for shock. Remember that known or suspected abuse carries with it a mandatory reporting responsibility.

Special Populations

If a pregnant woman is assaulted or otherwise injured, this may result in injury to the fetus, or the fetus may be harmed indirectly as a result of the woman’s blood loss. By 20 weeks of gestation, the top of the uterus has grown to the level of the patient’s belly button, making the fetus more susceptible to injury.

Special Considerations for Trauma and Pregnancy

Trauma is a serious complicating factor in pregnancy, partly because of the many physiologic changes that occur during pregnancy, but mostly because of the involvement of two patients: the woman and her fetus. Both patients are particularly vulnerable to trauma because of the unique features of pregnancy. The major causes of injury to pregnant women are motor vehicle crashes, falls, domestic abuse, and penetrating injuries such as gunshot wounds.

When a pregnant woman is involved in a motor vehicle crash or a similar mechanism of injury

(MOI), severe hemorrhaging may occur from injuries to the pregnant uterus.

The anatomic changes during pregnancy have important implications for trauma. As the woman approaches term, her abdominal contents are compressed into the upper part of the abdomen. There is a higher incidence of abdominal injuries associated with chest trauma. Meanwhile, because the peritoneum is maximally stretched, substantial abdominal trauma may occur without peritoneal signs.

In the second and third trimesters of pregnancy, the uterus is more vulnerable to trauma. The bladder is displaced upward (superior) and forward (anterior) and is therefore at increased risk of injury, particularly from a deceleration injury. Deceleration forces may bring about abruptio placentae or **uterine rupture**.

A relative redistribution of blood volume also occurs during pregnancy, with blood flow to the pelvic region increasing tenfold. Therefore, if a pregnant woman sustains a pelvic fracture, her chances of bleeding to death are much higher than those of a nonpregnant woman. A substantial amount of blood can be lost before signs and symptoms of shock develop because other mechanisms are compensating for the loss.

Recall that a pregnant woman has an increased need for oxygen. If she should need artificial ventilation, you will have to administer supplemental oxygen at a higher minute volume than usual (she will require a slightly faster rate of ventilation). Also remember that with the gravid uterus placing pressure on the stomach, the chances of vomiting and aspiration are dramatically increased.

Pregnant women have an increased risk of falls compared with nonpregnant women. Hormonal changes “loosen” up the joints in the musculoskeletal system, and the weight of the uterus and displacement of abdominal organs can change the patient’s balance.

Increases in blood volume, cardiac output, and in the resting pulse rate during pregnancy make it more difficult to interpret tachycardia. Furthermore, because of the pregnant woman’s vastly expanded blood volume, other signs of hypovolemia, such as a falling blood pressure, may not be evident until she has lost as much as 40% of her blood volume. Therefore, you need to aggressively treat a pregnant woman who has an MOI that indicates shock.

The muscular wall of the uterus acts as a cushion for the fetus against the direct effects of blunt trauma, but fetal injury can occur. The most common cause of fetal death from trauma is maternal death, but a woman will often survive an incident that proves fatal for the fetus. For instance, blunt trauma resulting in abruptio placentae has a good statistical outcome for pregnant women but often results in fetal death.¹⁴

If a pregnant woman has sustained trauma and is bleeding massively, the maternal circulation will shunt blood away from fetal circulation to maintain maternal homeostasis; maternal circulation takes precedence over the requirements of the fetus. Therefore, any injury that involves substantial maternal bleeding will threaten the life of the fetus. By the time the woman shows clinical signs of shock, fetal circulation will be so compromised that you can expect a fetal mortality rate of 70% to 80%.

Words of Wisdom

When the body encounters a catastrophic event (shock) threatening the life of a pregnant woman, the fetus is treated as a parasite by the woman’s body. The best hope of a positive outcome for the fetus is aggressive treatment of the woman.

Words of Wisdom

In a pregnant patient who has sustained trauma, remember to assess first for exsanguinating hemorrhage (follow the XABCDE mnemonic [eXsanguinating hemorrhage, Airway, Breathing, Circulation, Disability, Exposure]).

Finally, not all pregnant women properly position their seat belts when in a vehicle. The lap belt should be placed under the abdomen and over the hip bones, and the shoulder belt should be positioned between the breasts. If a pregnant woman is involved in a motor vehicle crash with an improperly positioned seat belt, the seat belt can cause harm to the woman and fetus because the seat belt compresses the uterus. Shoulder restraints, by contrast, decrease the chance of uterine injury.

Assessment and Treatment of the Pregnant Trauma Patient

A pregnant woman involved in a motor vehicle crash, fall, assault, or other injury must be evaluated in the emergency department (ED). In general, what is good for the woman will be good for the fetus. For example, any effort to improve maternal perfusion will improve fetal circulation. Potential damage to the fetus cannot be adequately assessed in the field. Whereas a decreased fetal heart rate signals an emergency situation, a normal fetal heart rate does not guarantee that all is well.

In general, the prehospital management of pregnant women with abdominal trauma is the same as for nonpregnant patients. Airway, breathing, and circulation remain the highest priorities.

In addition to abdominal tenderness, the examination of an injured pregnant woman may reveal an abnormal fetal position, an easily palpated fetus, inability to palpate the top of the uterus, or vaginal bleeding.

Carefully assess a pregnant woman's abdomen and chest for seat belt marks, bruising, and obvious trauma. Maintain a high index of suspicion for internal abdominal bleeding in the woman and possible direct injury to the fetus, regardless of seat belt placement.

Remember to treat the woman aggressively if there is an index of suspicion for injury. This is your only opportunity to provide optimal care for the fetus. Assess the abdomen for rigidity and question the woman about movement of the fetus since the accident.

Remember that the likelihood of domestic abuse increases greatly during a woman's pregnancy; maintain suspicion for evidence of abuse.

Because the large uterus can compress the inferior vena cava (decreasing right atrial preload), a pregnant woman should be transported to the hospital on her left side or with her right hip elevated about 6 inches (15 cm) to minimize the pressure of the inferior vena cava depending on the degree of suspicion for spinal column injury. The fetus may be in shock before signs appear in the woman, so initiate early, aggressive fluid resuscitation.

In summary, field treatment of a pregnant trauma patient is as follows:

1. **Maintain an open airway.** A pregnant patient has an increased risk of vomiting and

aspiration compared with patients who are not pregnant. Be prepared for and anticipate vomiting; keep your suction unit readily available. If the patient is unresponsive, call for paramedic backup to provide early endotracheal intubation to isolate the airway.

2. **Administer high-flow oxygen.** A pregnant woman's oxygen needs are 10% to 20% higher than normal, so provide 100% supplemental oxygen via a nonrebreathing mask if the patient is responsive.
3. **Ensure adequate ventilation.** Listen to breath sounds, and confirm that bilateral breath sounds are present. If the patient has inadequate ventilation, provide or assist ventilation with a bag-mask device and 100% oxygen. Because the uterus of a pregnant woman presses up against the diaphragm, she will be more difficult to ventilate.
4. **Assess circulation.** Control external bleeding promptly with direct pressure. Maintain a high index of suspicion for internal bleeding and shock based on the MOI because a pregnant patient will not always display typical signs and symptoms of shock. Keep the patient warm. Splint any fractures. Provide spinal immobilization if there is an indication and remember to tilt the board to the left to take pressure off the inferior vena cava.
5. **Provide IV fluids.** Start one or two IV lines of normal saline. Use large-bore catheters and macrodrip sets. Administer a bolus if signs and symptoms of hemodynamic compromise are present, with the goal of maintaining blood pressure above 80 mm Hg. Remember that a larger volume of fluid is necessary for the pregnant patient.
6. **Transport considerations.** Transport the woman on her left side (to anticipate vomiting and to avoid supine hypotensive syndrome). If she is on a backboard, tilt the backboard 30° to the left by wedging pillows beneath it. This will cause the uterus to shift, taking the weight off the inferior vena cava and improving venous return to the heart. Call early for assistance or a medical helicopter for significant MOIs or major traumatic injuries. Transport the patient to a trauma center if one is available in your area. Give early notification that you have a pregnant trauma patient in transport.

Because of the change in anatomy with the increasing size of the fetus, managing the airway becomes more challenging. There is greater pressure on the diaphragm and airways. Call early for paramedic backup for airway management and medication administration.

Finally, in any case of substantial vaginal bleeding or severe abdominal pain, quickly assess and transport the patient, support the airway, administer high-flow oxygen, place sanitary pads against the vaginal opening, position the patient on her left side, and call for paramedic backup.

Maternal Cardiac Arrest

If cardiac arrest occurs, provide cardiopulmonary resuscitation (CPR), beginning with chest compressions, as you would for a nonpregnant patient. The 2020 CPR and Emergency Cardiovascular Care (ECC) guidelines from the American Heart Association recommend positioning the pregnant patient experiencing cardiac arrest in a supine position while another rescuer provides manual left uterine displacement.¹⁵ Hand placement for chest compressions in an obviously pregnant patient should be in center of the chest, which is the lower half of the sternum. Additionally, the normal landmarks you would use for chest compressions may not be obvious in a pregnant patient in the third trimester—use the sternal notch as a guideline for hand placement (approximately 5 to 7 inches [13 to 18 cm] below the angle of Louis). This is shown in Chapter 15, *BLS Resuscitation*.

Once the patient arrives at the hospital, an emergency cesarean section may be performed. A cesarean section may be the only chance for a term or near-term fetus to survive. A pregnant patient with trauma who is in cardiac arrest requires rapid transport and early notification to the hospital. Even if the woman has *obvious* mortal injuries (eg, open head trauma with missing brain matter), good CPR and ventilatory support may keep the fetus viable until a cesarean section can be performed.

Cultural Value Considerations

The United States is among the most culturally diverse nations in the world. This diversity may be a factor when you are assessing and treating an obstetric patient from a culture different from yours.

Women of some cultures may have a value system that will affect their pregnancy, the choice of how they care for themselves during pregnancy, and how they have planned the childbirth process. Some cultures may not permit a male health care provider, especially in the prehospital setting, to assess or examine a female patient. Different cultures may view pregnancy differently than you do in terms of social, psychological, and emotional issues. Some may see pregnancy as a means of achieving status and recognition within the family unit, whereas others may experience a decrease in self-esteem. Your responsibility is to the patient and is limited to providing care and transport. You should respect these differences and honor requests from the patients.

Teenage Pregnancy

The United States has high teenage pregnancy rates compared with other developed countries.¹⁶ During your career, you are likely to respond to a pregnant teenager who may or may not be in labor. Adolescents present their own challenges to the EMS community in terms of physical and psychological development, even when pregnancy is not a contributing factor for a female teenager.

Pregnant teenagers may or may not know that they are pregnant or may be in denial about their pregnancy. As you begin to assess all female teenagers, you should remember that pregnancy is a possibility, as you would for any woman of childbearing

Special Populations

Often, adolescents who become pregnant are frightened and neglect to tell their parents or caregivers about their pregnancy, resulting in a lack of prenatal care. It is not uncommon for pregnant adolescents to skip meals to avoid gaining excess weight in an attempt to hide the expanding waistline. Lack of medical attention, poor diet, and a lifestyle that is not conducive to pregnancy (eg, use of recreational drugs and smoking) can result in danger to the adolescent or the fetus. Other emergencies may occur when the adolescent, without financial resources, tries “home remedies” to induce an abortion. It is important to question any female of childbearing age about the possibility of pregnancy, regardless of the chief complaint. Be sure to interview the patient in private where she will be more likely to confide in you.

age. The pregnancy itself may or may not be related to the nature of the call, but you should consider the possibility when assessing the patient, talking to the patient, obtaining a history, and providing treatment. Respect the teenager's privacy and need for independence. If possible, perform your assessment and obtain the patient's history in a location away from her parents.

Patient Assessment

In most cases, childbirth is a natural process that does not require your assistance. When childbirth is complicated by trauma or other conditions, any interventions you provide for the patient will benefit the fetus. For example, if a pregnant patient has a low pulse oximetry reading, the fetus does as well; applying oxygen to the patient also improves the oxygen level in the fetus.

Understanding certain terms unique to pregnancy will allow you to more accurately communicate the patient's obstetric history with other health care providers. **Gravida** is a term used to describe the number of times a woman has been pregnant. **Para** is a term used to describe the number of times a pregnant woman has delivered a viable newborn, one carried for more than 20 weeks' gestation. For example, if a woman has been pregnant twice, but had a miscarriage during her first pregnancy and one healthy child, she would be gravida 2, para 1. A woman who is pregnant for the first time would be gravida 1, para 0. After she delivers a viable baby, however, she then becomes gravida 1, para 1. A woman's history of pregnancy may be documented with G (gravida), P (para), and A (abortive history). For example, a woman who has had two pregnancies, one of which resulted in a viable newborn and one of which miscarried, this would be documented as G2P1A1. Some other commonly encountered obstetric terms are as follows:

- **Primigravida**—a woman who is pregnant for the first time.
- **Primipara**—a woman who has had only one delivery.
- **Multigravida**—a woman who has been pregnant two or more times, irrespective of the outcome.
- **Nullipara**—a woman who has never delivered a viable newborn, although she may have been pregnant before.

- **Multipara**—a woman who has delivered two or more viable newborns.
- **Grand multipara**—a woman who has delivered five or more viable newborns.

Scene Size-up

As with every emergency call, your safety is the top priority when dealing with an obstetric case. Take standard precautions; gloves and eye protection are a minimum if delivery has already begun or is imminent. If the call will result in a field delivery, you should also don a mask and gown. Consider calling for additional or specialized resources.

You will also encounter pregnant patients who are not in labor, so it is important to determine the MOI or nature of illness in a pregnant patient. Because a pregnant woman's balance may be altered by the weight and size of the fetus and hormones that relax the musculature, falls and spinal immobilization must be considered.

Safety

It is important that you always follow standard precautions to protect yourself from exposure to body fluids. There is a high potential of exposure to body fluids during childbirth.

Primary Survey

The primary survey with a pregnant patient is the same as with any patient: assess the ABCDEs (Airway, Breathing, Circulation, Disability, and Exposure), and manage life threats.

The general impression is a good across-the-room assessment that should tell you whether the patient is in active labor or if you have time to assess for imminent delivery and address other possible life threats. The chief complaint may be, "The baby is coming!" Take a moment to confirm whether the infant will be delivered in the next few minutes or whether you have time to continue to evaluate the situation. When trauma or other medical problems such as vaginal bleeding or seizures are the presenting complaint, evaluate these first and then assess the effect of these problems on the fetus. Use the AVPU (Awake and alert; responsive to Verbal

stimuli; responsive to Pain; or Unresponsive) scale to determine the patient's level of consciousness.

During an uncomplicated birth, life-threatening conditions with the woman's airway and breathing are not usually an issue. In contrast, a motor vehicle crash, an assault, or any number of medical conditions in a pregnant woman may cause a life threat to exist and, sometimes, result in a complicated delivery. In these situations, assess the airway and breathing to ensure they are adequate. If needed, provide airway management and oxygen as appropriate.

Recall that normal changes in pregnancy result in increased overall blood volume, increased heart rate, and changes in blood clotting. These changes can have a substantial effect on a pregnant patient who is bleeding, regardless of the cause. Quickly assess for any potential life-threatening bleeding, and begin treatment immediately. Assess the skin for color, temperature, and condition, and check the pulse to determine whether it is too fast or too slow. If there are signs of shock, control the bleeding, give oxygen, and keep the patient warm. A minimum of one IV line should be established in preparation for a fluid bolus if needed.

If delivery is imminent, prepare to deliver at the scene. The ideal place to deliver an infant pre-hospitally is in the security of your ambulance or the privacy of the woman's home. The area should be warm and private with plenty of room to move around.

If the delivery is not imminent, prepare the patient for transport and perform the remainder of the assessment en route to the ED. Administer oxygen. Pregnant women in the last two trimesters of pregnancy should be transported lying in the left lateral recumbent position to displace the weight of the uterus from the inferior vena cava, if possible. Although the left lateral recumbent position is an accepted treatment and transportation option, if the woman does not develop supine hypotension and is more comfortable in a supine position, it is acceptable to use a supine position. If spinal immobilization is indicated, secure the woman to the backboard and elevate the right side of the board with rolled towels or blankets to prevent supine hypotensive syndrome (**FIGURE 35-8**). Provide rapid transport for pregnant patients who have substantial bleeding and pain, are hypertensive, are having a seizure, or have an altered mental status.

FIGURE 35-8 Place a blanket under the right side of the backboard to prevent supine hypotensive syndrome in pregnant patients.

Words of Wisdom

Avoid tunnel vision when assessing a woman in labor. Remember, the ABCs still come first. Do a complete assessment including SAMPLE (Signs and symptoms, Allergies, Medications, Pertinent past medical history, Last oral intake, Events leading up to the illness or injury) history, vital signs, obstetric history, and recent fetal movement.

History Taking

When you are assessing a pregnant patient, determine the patient's chief complaint, and elaborate on the chief complaint using the OPQRST-I (Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, and Interventions) mnemonic. Specifically, you want to know if the patient is pregnant, how many times she has been pregnant (gravida), and how many times she has had a live birth (para). The first question ("Are you pregnant?") can generally be bypassed if the patient is obviously pregnant. Asking a woman who is near term if she is pregnant (the unspoken implication is that she is obese) is not a good way to develop patient trust, but, if in doubt, ask. The number of times a woman has been pregnant may also need to be clarified because some women may not count abortions or miscarriages as pregnancies. Also ask about the length of gestation and her estimated due date or date of confinement. You should also ask about fetal movement.

If the patient tells you she has abdominal pain, ask her to describe the pain; this information will help determine whether she is having contractions.

Has the woman had a baby before? Labor in a woman who is pregnant for the first time usually proceeds more slowly and takes longer (average time, 16 hours) than in subsequent pregnancies, allowing more time for transport. If the patient has already had a child, she may be able to tell you when she is about to deliver. If she believes that she is ready, examine for crowning and, if indicated, make immediate preparations for delivery.

Identifying potential complications prior to the delivery will better prepare you to treat the woman and newborn. Ask the patient whether she has experienced complications with any of her pregnancies, or whether she has had any obstetric or gynecologic complications. In addition, ask the following:

- Has she ever had a cesarean section? If so, is the current delivery planned for as a cesarean delivery or does the patient intend to have a vaginal birth after cesarean (VBAC)? (Complications of VBAC can include uterine rupture.¹⁷⁻¹⁹)
- Is the patient currently under a physician's care?
- Has she been taking prenatal vitamins?
- When was her last visit to her physician?
- Has her physician indicated any concerns about this pregnancy?
- Has the patient recently undergone ultrasonography? If so, what were the findings? Did the ultrasonogram reveal more than one fetus or any abnormal presentations?
- Is the patient taking any current medications? Any over-the-counter drugs, recreational drugs, or herbal supplements?
- Does the patient have any allergies?

Consider delivering a newborn at the scene under the following circumstances:

- Delivery is expected within a few minutes.
- A natural disaster, bad weather, or some other type of catastrophe makes it impossible to reach the hospital.
- No transportation is available.

To determine whether delivery may occur within a few minutes, first look for **crowning**, then ask the pregnant woman the following questions:

- How many weeks pregnant are you and when are you due? (The more premature the infant,

the more resuscitation and care it is likely to require. Knowing the gestational age can also help you select the correct-size equipment for the newborn.)

- Is this your first baby?
- Are you having contractions? How far apart are the contractions? How long do the contractions last? (Contractions are timed from the beginning of one contraction until the beginning of the next. If they are less than 5 minutes apart and regular, delivery may be imminent.)
- Do you feel the urge to move your bowels? (This indicates that the fetus has entered the birth canal and is resting on top of the woman's rectum.)
- Have you had any spotting or bleeding? If so, what color was it and how much? (Be sure to take any tissue that may have been passed during the bleeding with you to the hospital for evaluation.)
- Have you had a rush of fluid from the vagina? (This indicates that the membranes have ruptured.)

Do not allow the pregnant woman to get up to go to the bathroom. Instead, reassure her that the sensation of needing to move her bowels is normal and that it means she is about to deliver.

Also consider asking the following questions:

- Have you had a complicated pregnancy in the past?
- Do you use illicit (recreational) drugs, drink alcohol, or take any medications? (Many depressant drugs and alcohol pass through the placental barrier to the fetus. If they have been recently ingested, the newborn may be born with respiratory depression and require aggressive resuscitation.)
- Have you recently undergone ultrasonography, and is there a possibility that this is a multiple birth? (Multiple births are often lower in birth weight, and if they require invasive care, you may need additional assistance for each newborn in addition to the woman.)

If the patient's water has broken, ask about the color of the fluid and whether it had an odor. If it is brown or black or has a strong odor, it may be an indication of meconium staining. **Meconium**, a thick, tarry substance, is the fetus's first bowel movement and can pass into the amniotic fluid.

If meconium is present after birth, you should call early for paramedic backup; they may need to perform more invasive suctioning of the newborn's trachea (discussed later in this chapter).

Special Populations

A fetal heart rate of less than 120 beats/min likely means fetal distress. The length of time that a decreased fetal heart rate is sustained is another factor related to fetal distress.

Secondary Assessment

Your physical exam should be based on the patient's chief complaint. Just because a woman is pregnant, you should not rule out the possibility of other emergencies such as asthma, heart attack, or allergic reactions, for example. No matter what the chief complaint, the secondary assessment should include a complete set of vital signs including pulse; respirations; skin color, temperature, and condition; blood pressure; and pulse oximetry if time permits. Also obtain fetal heart tones and heart rate. By feeling the abdomen, you can roughly palpate the fetal position as well as assess fetal movement. Pay close attention to the vital signs of both patients—the woman and the fetus. Watch for tachycardia and hypotension (which could mean hemorrhage or compression of the inferior vena cava) or hypertension (possibly indicating preeclampsia). Compare your findings with previous blood pressure readings she may know of from prenatal visits. Hypertension, even mildly elevated blood pressure, may indicate more serious problems.

Words of Wisdom

Deep palpation of the abdomen in any woman with third-trimester bleeding may result in massive hemorrhage if she has placenta previa.

During the onset of labor, initial uterine contractions are often irregular. The woman may feel only a backache or abdominal cramping. As the labor progresses, the frequency and intensity of contractions increase. The full-term delivery usually

TABLE 35-1 False Labor Versus True Labor

Parameter	True Labor	False Labor
Contractions	Regularly spaced	Irregularly spaced
Interval between contractions	Gradually shortens	Remains long
Intensity of contractions	Gradually increases	Stays the same
Effects of analgesics	Do not abolish the pain	Often abolish the pain
Cervical changes	Progressive effacement and dilation	No changes

© Jones & Bartlett Learning.

occurs when the contractions are 1 to 2 minutes apart and last from 30 to 60 seconds. Some women may experience **Braxton-Hicks contractions**, which are irregularly spaced contractions that are more uncomfortable than painful and that do not increase in frequency or otherwise follow the course of true labor contractions. They can occur any time during pregnancy but are usually seen in the third trimester. This condition is also known as false labor. Because you have no way of telling in the field if a patient's contractions are from a miscarriage or another complication of pregnancy, the patient needs to be transported to the ED. The pains of true labor are regularly spaced and increase in intensity over time. **TABLE 35-1** lists the characteristics of false labor and true labor.

For a pregnant patient in labor, your physical examination should focus on contractions and possible delivery. Women who are pregnant for the first time typically take longer to deliver, whereas multigravida and multipara women can deliver very quickly. Assess the length and frequency of contractions by asking the patient and by placing your hand on the abdomen. Compare what you feel with the patient's experience during each contraction. If at any point you suspect delivery is imminent, you should check for crowning. This specific assessment should be performed only when appropriate and according to local protocol. If you do not suspect an imminent delivery and the patient has other complaints unrelated to delivery, you should not visually inspect the vaginal area.

Be sure to protect the woman's privacy during the physical examination.

If you see bleeding or discharge, ascertain when it started and check the abdomen for tenderness and rigidity. Normal abdomens are not rigid during pregnancy. Assessment of the serial vital signs will tell you if the woman or fetus is in distress.

Reassessment

As time allows, repeat the primary survey with a focus on the patient's ABCs and vaginal bleeding, particularly after delivery. Obtain another set of vital signs and compare the results with those obtained earlier. Frequent reassessment of vital signs may identify hypoperfusion from excessive blood loss as a result of delivery. Recheck interventions and treatments to see whether they were effective. Is the vaginal bleeding slowing with uterine massage? Uterine massage, discussed later in this chapter, can be used to slow vaginal bleeding after delivery. Finally, transport to an appropriate facility.

If your assessment determines that delivery is imminent, notify staff at the receiving hospital. Provide an update on the status of the woman and newborn after delivery. On the rare occasion that the delivery does not occur within 30 minutes or you determine that a complication is occurring that cannot be treated in the field, notify the hospital staff of your findings and provide rapid transport. Be sure to notify staff at the receiving hospital of all relevant information so there is time to prepare. The information you provide may help the hospital staff determine whether the patient will be seen in the ED or whether you will be asked to bring the patient directly to the labor and delivery unit.

For a pregnant patient with complaints unrelated to childbirth (such as trauma or difficulty breathing), be sure to include the pregnancy status of your patient in your radio report. The hospital staff will want to know the number of weeks of gestation, her due date, and any known complications of the pregnancy.

Thorough documentation is essential, especially the status of the newborn if delivery occurred in the field. You will have two patient care reports to complete. Obstetrics is among the most litigated specialties in medicine; this is another reason why scrupulous documentation is essential.

Assessment Pearls

- Every pregnant patient who has been in a motor vehicle crash must be evaluated at the hospital, even if injuries appear minor. Also note placement of seat belts, which may give clues to possible uterine compression and injury to the fetus.
- Obtain a thorough history of pregnant patients. Insights such as problems detected during prenatal screening, multiple births, or issues relating to hypoglycemia or drug or alcohol use will give you clues as to what to expect.
- As a newborn delivers, you must divide your attention between two patients. Designate one member of the crew to provide primary care to each patient. Call for help early if you suspect that both patients will need special care or that one will require resuscitation.
- Make sure to note the exact time of birth.
- Obtain an Apgar score at 1 minute and 5 minutes after birth.
- Notify the hospital early for signs of meconium staining.
- The base of the umbilical cord is the easiest place to palpate a pulse in a newborn.
- For a newborn with a heart rate of less than 100 beats/min, provide positive-pressure ventilations. If heart rate drops below 60 beats/min, begin chest compressions.
- If ventilations of a newborn do not appear effective, occlude the pop-off valve of the bag-mask device to increase pressure and help force fluid-filled alveoli open.
- Be judicious when administering IV fluid. Increasing blood pressure may also increase bleeding. Titrate fluid to maintain a palpable radial pulse.

Assessment and Management of Nondelivery Emergencies

Spontaneous Abortion

If spontaneous abortion occurs during the first half of the pregnancy, it is generally characterized by vaginal bleeding and abdominal cramping. Severe pain is rarely a presenting complaint because uterine contractions are not rhythmic, and the cervix remains closed. In the second half of pregnancy, the patient may present with severe abdominal pain caused by strong uterine contractions, substantial vaginal bleeding, and cervical dilation.

There is no specific treatment that you must provide to the patient with a suspected spontaneous abortion. The patient should receive high-flow oxygen, a large-bore IV line of an isotonic crystalloid (ie, normal saline or lactated Ringer solution) in the event fluid boluses are required for severe bleeding and shock, and transport to an appropriate hospital. You should support her emotionally, without giving false hope, and try to keep her calm.

Third-Trimester Bleeding

When the patient presents with the chief complaint of vaginal bleeding in the third trimester of pregnancy, try to determine as much as possible about the nature of the bleeding by asking the following questions:

- When did the bleeding start?
- What activity was the woman engaged in at the onset (ie, was she active or at rest)?
- How much blood has been lost (how many pads soaked)?
- Is the patient experiencing abdominal pain? If so, what is the nature of the pain? Is it sharp, cramping, dull, achy?

Use the OPQRST mnemonic to elaborate on the chief complaint of pain. Rate the severity of pain

on a scale of 1 to 10. During the physical examination, identify any changes in orthostatic vital signs. Orthostatic changes indicate a substantial blood loss, which may be contrary to the physical evidence of bleeding, which may be slight. Look for a positive Grey Turner sign (ecchymosis of the flanks) or Cullen sign (ecchymosis around the umbilicus), which can indicate the presence of internal bleeding.

You do not need to identify the underlying cause of the bleeding in the third trimester of pregnancy to begin treatment. Regardless of the source of hemorrhage, prehospital management is the same as follows:

1. Keep the patient in a recumbent position on her left side.
2. Administer 100% supplemental oxygen via a nonrebreathing mask at 15 L/min.
3. Provide rapid transport to a definitive care facility, notifying the facility of the patient's condition en route.
4. Start an IV line of normal saline with an 18-gauge IV catheter. Begin infusing a 250-mL bolus of fluid and then reevaluate. Continue with such boluses as indicated up to four boluses. If blood pressure has not yet reached 80 mm Hg systolic, obtain medical direction and prepare to administer additional fluid boluses. An additional IV line may be indicated.

YOU are the Provider

Part 3

While assessing the patient you note the baby's head crowning and make the determination to deliver on scene. You prepare for immediate childbirth by placing the sterile drapes in their appropriate positions and reminding the woman to breathe through the contractions. Your partner calls for a second ambulance for assistance. Placing your hand gently against the baby's head to prevent an explosive delivery, the baby starts to deliver. As the baby's head emerges, you note that the umbilical cord is around the neck.

Recording Time: 6 Minutes

Respirations	32 breaths/min, rapid
Pulse	Strong and regular, 120 beats/min
Skin	Warm and dry
Blood pressure	96/54 mm Hg
Oxygen saturation (SpO₂)	99% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. What are the possible complications if you do not support the baby's head?
6. How do you correct nuchal cord?

5. Obtain baseline vital signs. Do not attempt to examine the woman internally or pack the vagina with trauma pads.
6. Use loosely placed trauma pads over the vagina in an effort to stop the flow of blood. Massage the fundus if delivery has already occurred.
7. If bleeding is severe and signs and symptoms of shock are present, consider calling for paramedic backup to rendezvous en route.

Words of Wisdom

When starting an IV line on a patient in labor, try to choose a site other than the antecubital fossa. If the woman bends her arm to push during labor, the flow rate is cut off.

Ectopic Pregnancy

In cases of ectopic pregnancy, all the normal signs and symptoms of pregnancy are usually present. The patient is in severe pain, possibly in hypovolemic shock. The treatment of the patient with a suspected ectopic pregnancy is focused on supporting the ABCs. She should receive high-flow oxygen, at least one large-bore IV line of an isotonic crystalloid, and rapid transport to a hospital that can provide immediate surgery. If she is already in shock, she should receive 250-mL fluid boluses to maintain a minimum systolic blood pressure of 80 mm Hg and receive airway management as indicated.

Preeclampsia

Preeclampsia is characterized by the following signs and symptoms:

- Headache
- Swelling in the hands, face, and feet
- Anxiety
- Nausea/vomiting

In severe preeclampsia, you may also find the following:

- Pulmonary edema/shortness of breath
- Confusion or other altered level of consciousness
- Visual disturbances, such as blurry vision or scotomata (seeing spots)
- Upper abdominal pain
- **Myoclonus** (hyperactive reflexes)

Preeclampsia is most life threatening to the fetus and woman if seizures occur. If you suspect preeclampsia, it is important to obtain an accurate blood pressure. You should suspect preeclampsia if the blood pressure of a woman in her second or third trimester of pregnancy is above 140 systolic or 90 diastolic.

The treatment of a woman with preeclampsia is mostly supportive. You should ensure the ABCs and try to keep the patient calm. The patient should be kept in a position of comfort and monitored closely. At a minimum, she should receive supplemental oxygen to prevent fetal distress and an IV line of an isotonic crystalloid solution at a TKO rate for medication administration if it becomes necessary.

Words of Wisdom

If you are transporting a patient with suspected preeclampsia, be sure to keep the emergency lights and siren on the ambulance off and decrease sensory input as much as possible to avoid triggering seizure activity.

If a seizure occurs, you must protect the patient from being injured during the seizure. Administer oxygen and maintain an open airway. You should be ready to provide suctioning or other aggressive airway maneuvers, if necessary, including calling for paramedic backup.

Supine Hypotensive Syndrome

Supine hypotensive syndrome is most easily treated by placing the woman onto her left side, which causes the uterus to shift off of the inferior vena cava. This simple maneuver will cause an increase in venous return, preload, and therefore cardiac output, thereby increasing maternal blood pressure and perfusion. If the patient must be immobilized on the long backboard, you should place blanket rolls or something similar under the right side of the board.

Gestational Diabetes

Patients with gestational diabetes may be asymptomatic or may exhibit the same signs observed in patients with diabetes mellitus. Pregnant patients with a history of diabetes or who present with an altered mental status or seizures should have their

blood glucose level checked with a glucometer. Pre-hospital management should include high-flow oxygen, IV fluids, and administration of dextrose if indicated by a low blood glucose reading. Patients who are hyperglycemic should receive oxygen and IV fluid therapy per local protocol. Isotonic crystalloid fluid boluses may be necessary to treat the associated dehydration. Several fluid boluses may be required because diabetic ketoacidosis is commonly associated with severe hypovolemia, and possibly even shock.

Normal Childbirth

Stages of Labor

The onset of labor starts with contractions of the uterus. **Lightening** refers to the movement of the baby down into the pelvis prior to birth. Although lightening usually occurs prior to the onset of contractions, it may not happen until labor actually starts.

There are three stages of labor. The first stage begins with the onset of contractions and ends when the cervix is fully effaced and dilated.

The average length of the first stage of labor is 12 hours for a nulliparous woman and up to 8 hours for a multiparous woman. The second stage of labor is from the point of full cervical **effacement** (thinning and shortening of the cervix) and dilation (or crowning in the field) until the fetus is delivered. The average length of time for the second stage of labor is 1 to 2 hours for the nulliparous patient and 30 minutes for the multiparous patient.

Words of Wisdom

Labor occurs in three stages:

- **Stage 1.** Begins with the onset of contractions and ends when the cervix is fully effaced and dilated (or crowning)
- **Stage 2.** From the point of full cervical effacement and dilation (or crowning) until the fetus is delivered
- **Stage 3.** Begins with the delivery of the newborn and ends with the delivery of the placenta

The third stage of labor begins with the delivery of the newborn and ends with the delivery of the placenta. This stage takes an average of 30 minutes.

Occasionally the placenta is delivered immediately after the newborn is delivered.

Preparing for Delivery

When birth is imminent, you should prepare your equipment and position the patient for the delivery. Begin by administering oxygen as needed, if this has not already been done. If there is time, you should start a large-bore IV line of an isotonic crystalloid on the pregnant woman. IV access will be necessary if fluid boluses are needed for excessive postpartum bleeding.

After labor has begun, there is no way it can be slowed down or stopped in the field. Never attempt to hold the pregnant woman's legs together; doing so would only complicate the delivery and cause potential injury to the newborn.

If you decide to deliver the newborn at the scene, remember that you are only *assisting* the pregnant woman with the delivery. Your part is to help, guide, and support the newborn as it is born. Take standard precautions at all times. Limit distractions for yourself and for the patient. You want to appear calm and reassuring while protecting the patient's modesty. Recognize your own limitations; if you are unsure about what to do, contact medical control and provide rapid transport. If delivery must occur during transport, stop the vehicle and have your partner or partners assist with the delivery. After delivery of the newborn and any needed resuscitation have occurred, you may resume transport to the hospital.

Your emergency vehicle should always be equipped with one or more sterile emergency OB kits containing the following items (**FIGURE 35-9**):

- Surgical scissors or a scalpel
- Umbilical cord clamps
- A small rubber bulb syringe
- Towels, drapes, or sheets
- 4 × 4-inch (10 × 10-cm) and/or 2 × 10-inch (5 × 25-cm) gauze sponges
- Sterile gloves
- Infant blanket
- Sanitary pads
- Plastic bag

Two items that need to be available but are not usually included in the OB kit are an infant-size bag-mask device and goggles.

FIGURE 35-9 Your unit should contain a sterile obstetric kit.

© Jones & Bartlett Learning.

Patient Position

The patient's clothing and undergarments should be removed or pushed up to her waist. Cover her lower half with a sheet or blanket. Limit the patient's exposure and preserve her modesty as much as you can. If the emergency delivery is occurring at home, move the patient to the floor or other sturdy flat surface if she will allow it. You will find it easier to work on a firm surface padded with blankets, folded sheets, or towels rather than on a bed. Put a pillow or blankets beneath her hips to elevate them approximately 2 to 4 inches (5 to 10 cm). Support the patient's head, neck, and upper back with pillows and blankets. Have her keep her legs and hips flexed, with her feet flat on the surface beneath her and her knees spread apart, helping her to move into a semi-Fowler position (**FIGURE 35-10**). If delivery is occurring in an automobile, the patient should lie across the rear seat, with one foot on the floor and the other on the seat, with the upper knee and hip bent.

Track the progression of the delivery closely at all times. You do not want an abrupt delivery, when the head pops out uncontrollably, to occur. This could result in neck injuries or other injuries to the newborn.

Preparing the Delivery Field

Take the following steps to prepare the area where the newborn will be born:

1. If there is enough time, place towels or sheets on the floor around the delivery area to help soak up the amniotic fluid that will be released

FIGURE 35-10 The semi-Fowler position.

© Jones & Bartlett Learning.

when the amniotic sac ruptures and any blood that comes from the release of the mucus plug or during delivery. Determine if the amniotic sac has ruptured before you arrived.

2. Open the OB kit carefully so that its contents remain sterile (touch only the outside of the packaging).
3. Wash your hands thoroughly with a povidone-iodine or chlorhexidine scrub solution, if available.
4. Put on the sterile gloves, goggles, and gown.
5. Use the sterile sheets and towels from the OB kit to make a sterile delivery field. Place one sheet or towel under the patient's buttocks, and unfold it toward her feet (**FIGURE 35-11A**). The other sheet should be draped over her abdomen and upper legs. Alternatively, you can use three sheets as follows (**FIGURE 35-11B**):
 - One folded under the buttocks
 - One placed between the legs, just below the vagina
 - One placed across the abdomen

Words of Wisdom

There are only two instances when you should insert your hand inside the patient's vagina: in cases of breech delivery when the body delivers but the head is too large to fit through the pelvic inlet, and cord presentation (prolapsed umbilical cord).

FIGURE 35-11 Preparing the delivery field. **A.** Place sheets or towels under the woman, elevate the woman's hips, and support her head with one or two pillows. **B.** Use sterile sheets and towels from the obstetric kit to make a clean delivery field. Place one sheet under her buttocks, drape the other over her abdomen, and place drapes over the thighs.

© Jones & Bartlett Learning.

Delivering the Newborn

Your partner should be at the patient's head to comfort, soothe, and reassure her during the delivery. If she will allow it, administer oxygen. The patient may want to grip someone's hand. She may yell, cry, or say nothing at all. It is common for women to become nauseated during delivery, and some may vomit. If this occurs, have your partner turn the patient's head to the side so that her mouth and airway can be cleared with suction, as needed.

You must continually assess the patient for crowning. Do not allow an abrupt delivery to occur;

when labor is too fast, the tissues do not have enough time to stretch, and the patient is at risk for tears in the perineal area. Position yourself so that you can see the perineal area at all times. Time the patient's contractions from the beginning of one to the beginning of the next to determine their frequency. In addition, time the duration of each contraction by feeling the patient's abdomen from the moment the contraction begins (uterus and abdomen tightening) to the moment it ends (uterus and abdomen relaxing). Remind the patient to take quick, short breaths during each contraction but not to strain or push until ready to give birth. Between contractions, encourage the patient to rest and breathe deeply through her mouth.

Words of Wisdom

If the amniotic sac has not ruptured by the time the fetus's head is crowning, it will appear as a fluid-filled sac emerging from the vagina. This situation is potentially life threatening for the fetus because the sac will suffocate the fetus if it is not removed. You may puncture it with a clamp or tear it by twisting it between your fingers. As the sac is punctured, amniotic fluid will gush out. Push the sac away from the fetus's face as the head is delivered and wipe the mouth and nose with gauze. Use a bulb syringe to clear any fluid obstructing the mouth or nose. If the amniotic fluid has a green tint (indicating meconium staining) or has a foul odor, notify the receiving hospital. Meconium may result in respiratory distress or an airway obstruction in the newborn.

Words of Wisdom

If there is more than one fetus, immediately call for a second EMS unit. With a normal, single birth, you will have two patients: the woman and the newborn. Multiple births will require additional assistance.

SKILL DRILL 35-1 summarizes the steps to deliver the newborn.

A newborn's body temperature can drop very quickly. Therefore, as soon as the entire newborn is born, dry the newborn off. Wrap the newborn immediately in a blanket or towel, and place the newborn on one side, with the head slightly lower than

Skill Drill 35-1 Delivering a Newborn**Step 1**

Control the delivery. When crowning occurs, place gentle pressure on the newborn's head with the palm of your gloved hand to prevent the head from delivering too quickly and tearing the woman's vagina.

As the newborn's head begins to emerge from the vagina, it will start to turn. Support the head as it turns. Do not attempt to pull the newborn from the vagina! If the membranes cover the head after it emerges, tear the amniotic sac with your fingers or forceps to permit escape of amniotic fluid and enable the newborn to breathe.

Slip your middle finger alongside the newborn's head to check for a nuchal cord. If you find a nuchal cord, try to slip it gently over the newborn's shoulder and head. Should this maneuver fail, and if the cord is wrapped tightly around the neck, place umbilical clamps 2 inches (5 cm) apart and cut the cord between the clamps.

If the airway appears to be obstructed, cradle and support the newborn's head in your hand, and clear the airway by suctioning with the bulb syringe.

**Step 2**

Gently guide the head downward to allow delivery of the upper shoulder. Do not pull on the newborn to facilitate the delivery.

Skill Drill 35-1 Delivering a Newborn (*continued*)**Step 3**

Gently guide the head upward to allow delivery of the lower shoulder.

**Step 4**

After the shoulders are delivered, the newborn's trunk and legs will follow rapidly. Be prepared to grasp and support the newborn as it emerges. Handle the newborn firmly but carefully. Newborns will be slippery and usually covered with a harmless, white, cheesy substance called vernix caseosa.

After the newborn is delivered, maintain its body position at the same level as the vagina to prevent blood drainage from the umbilical cord.

Wipe any blood or mucus from the newborn's nose and mouth with a sterile gauze. If airway obstruction is noted, use the bulb syringe to suction the mouth and nostrils. Be sure to squeeze the bulb before inserting the tip, and only then place the tip in the newborn's mouth or nostril and release the bulb slowly. Withdraw the bulb, expel its contents into a waste container, and repeat suctioning as needed.

Dry the newborn with sterile towels (wet newborns lose heat faster than dry ones), and either wrap the newborn with a dry blanket or place skin-to-skin on the mother's abdomen to encourage breastfeeding.

Record the time of birth for your patient care report.

the rest of the body. Wrap the newborn so that only the face is exposed, making sure that the top of the head is covered. Make sure that the newborn's neck is in a neutral position to maintain an open airway. Newborns are extremely sensitive to cold, so if at all possible, you should warm the blanket or towel before you use it. Use a sterile gauze pad to gently wipe the newborn's mouth, and again suction the mouth and nose if needed. Suctioning the nose is particularly important because newborns breathe through their noses. If you prefer, you can pick up and cradle the newborn in your arm at the level of the woman's vagina while doing this, but always keep the head slightly downward to help prevent aspiration. After suctioning, keep the newborn at the same level as the woman's vagina until the umbilical cord is cut. If the newborn is higher than the vagina, blood will be siphoned back through the umbilical cord to the placenta, resulting in fetal hypovolemia.

Words of Wisdom

Keep a towel or sheet handy to wipe your hands and to help hold the newborn because the baby will be very slippery.

Apgar Scoring

The **Apgar score system** (devised by Virginia Apgar, MD) is a useful means of evaluating the adequacy of a newborn's vital functions immediately after birth; such information will prove useful to those who take over the care of the newborn after your delivery. In this system, five parameters—heart rate, respiratory effort, muscle tone, reflex irritability, and color—are each given a score from 0 to 2 first at 1 minute and again at 5 minutes after birth. Most newborns are vigorous and have a total score of 7 to 10; they cough or cry within seconds of delivery and require no further resuscitation. Newborns with a score in the 4 to 6 range are moderately depressed; they may be pale or blue 1 minute after delivery, with poorly sustained respirations and flaccid muscle tone. These newborns will require resuscitation. Neonatal resuscitation is discussed in detail later in this chapter.

Cutting the Umbilical Cord

After the newborn has been delivered and is breathing well, the umbilical cord can be clamped and cut

because it is no longer necessary for the newborn's survival. Clamping of the cord should be delayed 30 seconds after delivery for most vigorous term and preterm (34 to 36 weeks) newborns, unless the newborn requires resuscitation.²⁰ The steps are as follows:

1. Handle the umbilical cord with care. It tears easily.
2. After the cord has stopped pulsating, tie or clamp the cord approximately 4 inches (10 cm) from the newborn's navel, and then place the second tie (or clamp) 2 inches (5 cm) from the first tie. Cut the cord between the two ties or clamps.
3. Examine the cut ends of the cord to be certain there is no bleeding. If the cut end attached to the newborn is bleeding, tie or clamp the cord *proximal* to the previous clamp, and examine it again (do *not* remove the first clamp). There should not be any oozing from the newborn's end of the cord.
4. After the cord is clamped and cut, wrap the newborn in a dry blanket. If the woman's condition is stable, you may give the newborn to her allowing it to rest on her chest skin-to-skin. This will give her a chance to bond and she may want to begin breastfeeding the newborn. The suckling reflex triggers the uterus to contract, which will speed the delivery of the placenta and reduce bleeding.

By now, the newborn should be pink and breathing on their own. You can give the newborn, wrapped in a warm blanket, to your partner, and your partner can monitor the newborn and complete the newborn's initial care. You should reassess the woman and prepare for delivery of the placenta.

Words of Wisdom

A delay in clamping the umbilical cord and keeping the newborn below the placenta may allow blood to flow into the newborn, which can result in polycythemia (an abnormally high red blood cell count).

Delivery of the Placenta

The placenta is attached to the end of the umbilical cord that is coming out of the woman's vagina. As with the newborn, you need only assist with the

delivery. Usually the uterus will deliver the placenta within a few minutes of the birth, although it may take as long as 30 minutes. During this time you should reassess the woman and wait for the placenta to begin to separate spontaneously. Never pull on the end of the umbilical cord in an attempt to speed delivery of the placenta. This can cause tearing of the cord, the placenta, or both, and cause serious, perhaps life-threatening, hemorrhage. If the placenta has not delivered in the time it takes to reassess the woman, and in the time it takes to prepare both her and the newborn for transport, do not delay transport just to await the delivery of the placenta.

Words of Wisdom

Never pull on the umbilical cord. This could result in tearing or uterine inversion that can be detrimental to the woman.

The normal placenta is round, about 7 inches (18 cm) in diameter, and about 1 inch (2.5 cm) thick. It consists of two surfaces—one facing inward, called the fetal surface, and one facing outward, called the maternal surface. The fetal surface is smooth and covered with a shiny gray membrane. The maternal surface is rough, is divided into lobes, and is a dark red-brown color similar to raw liver. Wrap the entire placenta and umbilical cord in a towel and place them in a plastic bag. The placenta and remaining cord must be transported to the hospital. Hospital personnel will examine them to make certain that the entire placenta has been delivered.

Postpartum Care

After delivery of the placenta and before transport, place a sterile pad or sanitary napkin over the vagina and straighten the woman's legs. You can help to slow postpartum bleeding by gently massaging the uterine fundus with a firm, circular, kneading motion (**FIGURE 35-12**). The abdominal skin will be wrinkled and very soft. You should be able to feel a firm, grapefruit-sized mass in the lower abdomen; this is the fundus. As you massage it, the uterus will contract and become firmer. This may sometimes be uncomfortable for the woman. Reassure her and explain that it is necessary to help control the bleeding. If the woman chooses to breastfeed

FIGURE 35-12 After delivery, massage the woman's abdomen in a firm, circular motion.

© University of Maryland Shock Trauma Center/MIEMSS.

the newborn, this will also stimulate the uterus to contract. Massaging the uterus and having the newborn stimulate the woman's nipples by nursing will cause a release of **oxytocin**, a hormone produced in the posterior pituitary gland that will help to contract the uterus and slow bleeding. Take a minute to congratulate the woman and thank anyone who assisted. Be sure to record the time of birth in your patient care report.

Words of Wisdom

Allowing the woman to breastfeed or firmly massaging the fundus can help the uterus to contract and diminish bleeding.

After delivery of the newborn, obtain the woman's vital signs. Monitor the woman's condition closely for postpartum hemorrhage and shock, seizure activity, or respiratory difficulty. Determine whether the vaginal discharge following delivery (lochia) is the expected normal vaginal discharge of blood and mucus. This discharge is usually red in the first few days and will decrease in amount and change to a brown color for several weeks after delivery. The average blood loss during the third stage of labor is normally approximately 0.3 pints (150 mL). Some bleeding, usually less than 500 mL, occurs before the placenta delivers.

Postpartum Hemorrhage

When blood loss exceeds 1 pint (500 mL) during the first 24 hours after giving birth, it is considered

postpartum hemorrhage (bleeding after birth). Anything that interferes with the contractions of the interlacing uterine muscle fibers after delivery of the placenta may cause postpartum hemorrhage.

The following are emergency situations:

- The placenta has not delivered after 30 minutes.
- More than 500 mL of bleeding occurs before delivery of the placenta.
- Substantial bleeding occurs after the delivery of the placenta.

If any of these events occur, provide rapid transport of the woman and newborn to the hospital. Place a sterile pad or sanitary napkin over the woman's vagina to collect any blood; manage external bleeding from perineal tears with firm pressure. Never pack the vagina with dressings in an attempt to control the hemorrhage; these will only have to be removed at the hospital, and the bleeding is coming from a source that you cannot control. Treat the woman for shock according to local protocol, apply a blanket to keep her and the newborn warm, and administer oxygen and isotonic fluid boluses (250 mL) to maintain perfusion.

Complications of Labor

Occasionally you may be called to help a woman with an abnormal labor or delivery. These problems are rare, but can be life threatening for both the woman and fetus. The definitive treatment for many of these problems is a cesarean section; therefore, rapid transport to the hospital is crucial. The next sections will prepare you to provide the best care possible for patients with abnormal or complicated labors and deliveries and know when to initiate rapid transport rather than attempt delivery at the scene.

Preterm Labor

Labor (uterine contractions that are regular, intense, and accompanied by effacement) that begins after the 20th week of gestation but before the 37th week is considered preterm. The threat to the unborn fetus is a premature birth. Signs and symptoms are the same as normal childbirth labor. The treatment for a woman in preterm labor is to prevent labor from occurring, thereby allowing the fetus to more fully develop and have a better chance of survival. If the pregnancy is not near term, the

FIGURE 35-13 Premature newborns (at right) are smaller and thinner than term newborns (at left).

© American Academy of Orthopaedic Surgeons.

patient's physician may admit her to the hospital for medications, bed rest, and close monitoring. In the field, the best treatment option is a bolus of an isotonic crystalloid solution.

A newborn that delivers before 36 weeks of gestation or weighs less than 5 lb (2.25 kg) at birth is considered to be **premature**. A premature newborn is smaller and thinner than a full-term newborn, and its head is proportionately larger in comparison with the rest of its body (**FIGURE 35-13**). The **vernix caseosa** that is found on the full-term newborn will be missing on the premature newborn or will be minimally present. There will also be less body hair. Premature newborns are often deficient of surfactant, resulting in increased alveolar surface tension. Therefore, positive-pressure ventilations (PPV) may be difficult to perform. Be careful, however, and do not become overzealous while ventilating a premature newborn; doing so may result in a pneumothorax.

Any premature newborn needs special care, although as with any newborn, you should keep the premature newborn warm, dry, and positioned on the mother's chest. Keep the ambulance interior warm: between 90°F and 95°F (32.2°C and 35°C). Maintain the newborn's airway.

Administer supplemental oxygen through a tent above the newborn's head. Do *not* blast oxygen directly into the newborn's eyes. Use low flow (<4 L/min).

Prevent bleeding from the umbilical cord; a very small newborn cannot afford to lose even a small amount of blood. If the cord is oozing, apply another clamp.

Finally, prevent contamination. Premature newborns are highly susceptible to infection. Wear a surgical gown and mask, and keep bystanders at a distance, including any family members other than the mother.

You may have access to a specialized premature newborn carrier (isolette), which can be used for immediate care as well as transport. Fill the hot water bottles and pad them well so that they do not come into direct contact with the newborn's skin. Place one on the bottom of the carrier and one on each side of the space for the newborn. After you have wrapped the newborn in a blanket and placed it inside the carrier, secure the carrier inside the vehicle. If a special carrier is not available, you must keep the premature newborn warm with additional blankets, thermal packets, and a warmed patient compartment.

Postterm Pregnancy

Postterm means the pregnancy period is longer than 41 completed weeks of gestation. A true postterm pregnancy can lead to problems with both the woman and the fetus. Postterm fetuses can be larger

than a typical 40-week fetus, sometimes weighing more than 10 pounds (5 kg), which can lead to a more difficult labor and delivery and an increased risk of injury to the fetus as it travels through the birth canal. The likelihood of a cesarean section being required is increased and the woman is also at greater risk for perineal tears and infection.

Postterm newborns have an increased risk of meconium aspiration, infection, and being stillborn and may not have developed normally because of the restricted size of the uterus. The larger size of the fetus causes it to take up more space inside the uterus, resulting in compression of structures, including blood vessels of the placenta and the umbilical cord. Be prepared to resuscitate the newborn, as respiratory and neurologic functions may have been affected.

Fetal Distress

Many conditions may cause fetal distress, including hypoxia, nuchal cord, trauma, abruptio placentae, fetal developmental disabilities, and a prolapsed cord. It will be difficult for you to assess for fetal distress in the field. Most pregnant women will be

YOU are the Provider

Part 4

You feel around the baby's neck and find that the cord is loose enough to remove without clamping and cutting it. As you gently slip the umbilical cord from around the newborn's head, the body delivers, and you note the time to be 1429. The newborn is small and listless, but you do not see any signs of meconium staining. When the umbilical cord stops pulsating, you clamp and cut it. As you attempt to remember all of the steps of neonatal resuscitation, you recall that you need to "Do What Probably Seems Simple," which you recall to be Dry, Warm, Position, Stimulate, and Suction. You vigorously dry the patient remembering to change out towels frequently to ensure that the newborn remains warm. As you are warming the newborn, the second ambulance arrives and assumes care of the woman.

Newborn Assessment Recording Time: 1 Minute After Birth

Respirations	None
Pulse	120 beats/min, regular
Skin	Central cyanosis
Blood pressure	Not obtained
Oxygen saturation (SpO ₂)	Not obtained
Pupils	Not obtained

7. Why is it important to note the time of birth?
8. Why is it important to note whether there was meconium present on delivery?

acutely aware of how much or how little the fetus is moving. You should rely on the information provided by the woman; for example, she may report that the fetus is not moving or that movement is markedly decreased. Remember that the best care for the fetus is quality care for the woman. Provide support to the woman and rapid transport.

Uterine Rupture

If the uterus ruptures, it will happen during labor. Patients at greatest risk are women who have had several children and those with a scar on the uterus (eg, from a previous cesarean section). Typically, you will find a woman in active labor who is reporting weakness, dizziness, and thirst. She may tell you that she initially had very strong and painful contractions, but then the contractions slackened off and she now has severe abdominal pain. The abdomen may be rigid from peritonitis. Physical examination will reveal signs of shock—sweating, tachycardia, and falling blood pressure. Substantial vaginal bleeding may or may not be obvious. One possible sign of uterine rupture is being able to palpate fetal body parts through the abdominal wall.

High-Risk Pregnancy Conditions

Meconium Staining

While in utero, the fetus passively ingests several elements—for example, lanugo (fine, downy hair), mucus, and amniotic fluid. This material is stored in the intestines and constitutes the first stool the fetus passes. This first stool (meconium) is odorless, green-black, and has a tarlike consistency. Unlike later feces, it is also sterile. In cases of fetal distress, or with the stresses of labor and delivery, the fetus may expel the meconium into the amniotic fluid; this is termed **meconium staining**. If this occurs in utero, it can be aspirated into the fetus's lungs and may result in chemical pneumonia in the newborn. Umbilical cord prolapse is one condition that can cause such fetal distress and induce meconium expulsion if compression of the cord has occurred.

There is no way for you to ascertain whether meconium is in the amniotic fluid until the amniotic sac breaks. Normally, the amniotic fluid should be clear. A yellow tint to the amniotic fluid suggests the meconium has been in the amniotic fluid for a while. A green-black color, especially with the

presence of particulate matter, indicates recent passage of meconium and is a sign of danger.

You need to be vigilant regarding the need for suctioning if meconium staining is present and the newborn is not responding normally. The viscosity of meconium can cause the newborn's airway to become partially or completely blocked, and meconium trapped in the airways will irritate the respiratory tract, further hampering the newborn's efforts to breathe.

If the newborn is vigorously moving and is not presenting with indications of needing ventilation assistance, suctioning is not recommended. Call early for paramedic backup if meconium is present. Depressed newborns will require tracheal suctioning through an endotracheal tube if meconium is present in the airway.

Multiple Gestation

According to the CDC, the incidence of women carrying twins reached an all-time high in 2014 and began to decline in 2015.²¹ Odds are, you will have to assist in the delivery of multiple births at some point. The delivery of multiple births does not usually pose special problems, except that you have to do a few things twice (or more). Always keep a spare OB kit in your equipment.

The woman will usually know that she is carrying multiple fetuses, especially if she has had appropriate prenatal care. Consider the possibility of twins if the uterus is still large and firm after delivery of the first newborn. If you have reason to suspect there is more than one fetus, proceed as follows:

- Repeat the earlier preparations for delivery. If time permits, put on new gloves and a gown from the spare OB kit.
- Contractions will usually start again within about 10 minutes after the birth of the first newborn, and the second newborn can be expected to arrive within 45 minutes of its twin.
- Twins are usually delivered one at a time. When the first newborn is born, clamp and cut the cord approximately 30 seconds following birth and before the second newborn is delivered. Inspect *both* ends of the cord for oozing, and apply a second clamp if necessary, to prevent hemorrhage from the twin if there is a shared placenta (you will not know until the placenta delivers). Some twins share a placenta; others may have separate placentas or may share two

placentas that have fused into one. Usually both newborns are delivered before the first placenta is delivered.

- Given that twins tend to be smaller than single-term newborns, pay meticulous attention to keeping them warm, well oxygenated, and in as sterile an environment as possible.
- Identify the first newborn delivered as “Baby A” by loosely tying an extra length of tape around the foot. Record the time of birth of each twin separately. With the delivery of two or more newborns, you can indicate the order of delivery by writing on a piece of tape and placing it on the blanket or towel that is wrapped around each newborn.

Cephalopelvic Disproportion

In cephalopelvic disproportion, the head of the fetus is larger than the mother’s pelvis. In most cases, a cesarean section will be required to prevent maternal and fetal distress. Before you attempt delivery in the field, ask the patient if this complication was identified during prenatal care. Cephalopelvic disproportion may cause massive hemorrhage, along with other postpartum complications.

Intrauterine Fetal Death

On rare occasions, you may find yourself delivering a fetus who died in the woman’s uterus before labor. Good prenatal care most often identifies a dead fetus well before delivery, but in the absence of such care, it may be totally unexpected. Complications of labor and delivery can also result in death of the fetus, with the fetus dying in utero shortly before birth. This situation will test your medical, emotional, and social abilities. Grieving parents will be emotionally distraught and will require all your professionalism and support skills.

If intrauterine infection has caused the death, you may note an extremely foul odor. The delivered newborn may have skin blisters, skin sloughing, and a dark discoloration depending on the stage of decomposition. The head will be soft and perhaps grossly deformed.

Do not attempt to resuscitate an obviously dead newborn (ie, signs of petrification are evident). However, do not confuse such a newborn with newborns who have had a cardiopulmonary arrest as a complication of the birthing process. You must attempt to resuscitate normal-appearing newborns.

Amniotic Fluid Embolism

Amniotic fluid embolism is a life-threatening condition that is extremely rare and hardly ever seen in the hospital setting. Factors increasing the chance of this type of complication include maternal age greater than 35 years, eclampsia, abruptio placentae, placenta previa, uterine rupture, and fetal distress. Amniotic fluid embolism occurs when amniotic fluid and fetal cells enter the woman’s pulmonary and circulatory system through the placenta via the umbilical veins. This transfer may occur owing to ruptured membranes and ruptured cervical or uterine veins. Regardless of the cause, the result is an exaggerated response from the pregnant woman’s body (allergic reaction) that results in coagulopathies, cardiac and respiratory collapse, and eventually death.

Signs and symptoms include a sudden onset of respiratory distress and hypotension. Many of these patients are extremely cyanotic and have seizures. They eventually go into cardiogenic shock, become unresponsive, and may experience cardiac arrest. In patients who survive this initial reaction, coagulopathies (their blood loses the ability to clot) typically develop. Your treatment should focus on supporting the woman’s vital systems (respiratory and circulatory) and providing rapid transport. Treatment for the fetus is aimed at successful resuscitation of the woman and probable cesarean section delivery in the hospital.

Complications of Delivery

Breech Presentation

The presentation is the position in which a newborn is born. It is the part of the body that comes out first, also known as the presenting part. Most newborns are born head first, or a vertex presentation. Occasionally, the buttocks or both feet come out first. This is called a **breech presentation** (FIGURE 35-14). There are different types of breech presentations:

- **Frank.** Hips flexed and knees extended, with the buttocks as the presenting part
- **Incomplete.** One or both hips and knees may be extended, with one or both feet as the presenting part
- **Complete.** Hips and knees both flexed, with the buttocks as the presenting part

With breech presentation, the newborn is at greater risk for delivery trauma. Prolapsed umbilical

FIGURE 35-14 In breech presentation, the buttocks present first. Breech deliveries are usually slow, so you will often have time to transport the patient to the hospital.

© Jones & Bartlett Learning.

cords (discussed later in this section) are more common in breech deliveries. Fortunately, breech deliveries are usually slow, so there is time to get the patient to the hospital. If the newborn's buttocks have already passed through the vagina, delivery is under way, and you must prepare to assist. Call for paramedic backup if time allows. In general, if the woman does not deliver within 10 minutes of the buttocks presentation, provide rapid transport. You should have medical control guide you in this difficult situation.

The preparations for a breech delivery are the same as those for a vertex delivery:

- Position the patient, unwrap the emergency delivery kit, and place yourself and your partner as you would for a normal delivery.
- Allow the buttocks and legs to deliver spontaneously, supporting them with your hand to prevent rapid expulsion. The buttocks will usually come out easily. Let the legs dangle on either side of your arm while you support the trunk and chest as they are delivered.
- The head is almost always facedown and should be allowed to deliver spontaneously. If the delivery of the head stalls, you must keep the newborn's airway open: Make a "V" with

FIGURE 35-15 In rare instances, a newborn's limb, usually a single arm or leg, presents first. This is a serious situation, and you must provide prompt transport for hospital delivery.

© Jones & Bartlett Learning.

your gloved fingers and place them into the vagina. You must push the walls of the vagina away from the mouth and nose of the newborn. This is a true emergency and requires rapid transport. *A breech presentation in which the head will not deliver is one of only two circumstances in which you should put your fingers into the vagina; the other is in the event of a prolapsed cord.*

- Cover the newborn's body to maintain warmth during transport.

Special Populations

Any fetus that is not delivering headfirst or buttocks first must be managed at the hospital.

Limb Presentation

On rare occasions, the presenting part of the newborn is neither the head nor buttocks, but is a single arm, leg, or foot. This is called a **limb presentation** (**FIGURE 35-15**). You cannot successfully deliver such a presentation in the field; these newborns must

be delivered surgically in the hospital. If your patient has a limb presentation, you must transport the patient to the hospital immediately. If a limb is protruding, cover it with a sterile towel. Never try to push it back in, and never pull on it. Place the patient on her back with her head down and hips elevated. In this situation, you have two goals: (1) to prevent further trauma to the newborn that could result from the patient's continued pushing and (2) to transport the patient rapidly and safely to the hospital. Contact medical control and the receiving hospital to make certain they are prepared for your arrival. You should administer high-flow oxygen to the woman and closely monitor her condition en route.

Shoulder Dystocia

Another complication of delivery is **shoulder dystocia** or difficulty in delivering the shoulders. Women with diabetes, large fetuses, and fetuses that are postterm are at increased risk for this complication. Shoulder dystocia occurs after the head has been delivered and the shoulder cannot get past the woman's symphysis pubis; there is either difficulty in getting it to pass or it gets "stuck" behind the pelvic bones and the fetus is unable to be delivered. This unexpected complication is a threat to the life of the fetus if it is not delivered because of the increased chance of cord compression. As time passes and the shoulders are not clearing, the fetus cannot breathe (the lungs are still inside the birth canal) and/or the cord is compressed between the fetus and the woman's tissue. The delivery needs to be completed for the fetus to breathe. The major concern for the newborn after it is born is damage to the brachial nerve plexus.

There are several maneuvers that may be attempted in an effort to widen the woman's pelvis or reposition the fetus to allow for a successful delivery. The McRoberts maneuver is one of the safest (for woman and fetus) maneuvers to use in the case of shoulder dystocia. To widen the woman's pelvis and flatten the lower back, hyperflex her legs tightly to her abdomen. It may be necessary to apply suprapubic pressure (on the woman's lower abdomen) and to *gently* pull on the fetus's head.

Nuchal Cord

During delivery, the umbilical cord may become wrapped around the newborn's neck, a condition

called a **nuchal cord**. Nuchal cords occur in 15% to 34% of all births.²² In most cases, a nuchal cord is not a substantial problem, but as the fetus descends during labor, cord compression may occur, causing the fetal heart rate to slow and resulting in fetal distress. A nuchal cord that is wound tightly around the neck could cause the newborn to asphyxiate.

If you observe that the umbilical cord is wrapped around the newborn's neck, slip your finger under the cord and gently attempt to slip it over the newborn's shoulder and head. If this attempt is not successful or the cord is wrapped too tightly, you must cut it before the delivery can continue. Carefully place two umbilical clamps 2 inches (5 cm) apart on the cord and carefully cut the cord between the clamps in a motion going away from (not toward) the infant.

If the cord is wrapped more than once around the neck, a rare event, you must clamp and cut only once. After you have cut the cord, unwrap it from around the neck. Handle the cord carefully; it is fragile and easily torn. If the cord does tear, severe hemorrhage can occur from the mother, newborn, or both. Fortunately, the cord is usually not wrapped around the newborn's neck and does not have to be clamped and cut until after the entire newborn has been born. However, you must always check for the presence of a nuchal cord.

Prolapsed Umbilical Cord

Prolapsed umbilical cord is a rare presentation in which the cord emerges from the uterus ahead of the newborn, for example, when the amniotic sac ruptures. With a prolapsed umbilical cord, the blood supply to the newborn may be interrupted (**FIGURE 35-16**). As the newborn starts to exit the cervix, the cord will be pressed against the pelvis. This can slow or stop the blood supply to and from the newborn. This presentation requires surgical intervention.

Your goal in the treatment of this patient is to prevent the woman from pushing and compressing the umbilical cord. If possible, place the patient supine with her lower extremities elevated. You may also use pillows or folded sheets to accomplish this position. Alternatively, the patient may be placed in a knee-chest position: kneeling and bent forward, facedown (**FIGURE 35-17**). Either of these positions

FIGURE 35-16 A prolapsed umbilical cord, another rare situation, is dangerous and must be cared for at the hospital.

© Jones & Bartlett Learning.

FIGURE 35-17 When a patient has a prolapsed cord, place her on an incline with feet higher than the head or in the kneeling position shown here. These positions help keep weight off the cord.

© Jones & Bartlett Learning.

is meant to use gravity to help keep the weight of the newborn off of the prolapsed cord.

After the patient is positioned, insert a gloved hand into the vagina and gently push the presenting part away from the umbilical cord, back into the vagina until it no longer presses on the cord. *This is one of only two situations in which you should insert your hand into the vagina (the other is breech presentation in which the head will not deliver).* You should push with only enough pressure to keep the

pulsations in the umbilical cord. You should be extremely careful because too much pressure could cause head or neck damage to the newborn.

While you maintain pressure on the presenting part, have your partner cover the exposed portion of the cord with dressings moistened in warmed normal saline. Try to maintain that position, with a gloved hand pushing the presenting part away from the cord, throughout *urgent transport* to the hospital.

Postpartum Complications

Excessive Bleeding

Some bleeding always occurs with delivery, but bleeding that exceeds approximately 1,000 mL is considered high risk for maternal mortality and morbidity. If bleeding continues after delivery of the placenta, continue to massage the uterus, but check your technique and hand placement. Excessive bleeding after birth is usually caused by the uterus not fully contracting. Incomplete contraction may occur because the muscles that cause contraction are exhausted following delivery of more than one infant or a long labor process or because parts of the placenta remain in the uterus, blocking closure. Cover the vagina with a sterile pad. Do not discard any blood-soaked pads; hospital personnel will use them to estimate the amount of blood loss. Also save any tissue that may have passed from the vagina.

Administer oxygen as needed, monitor vital signs frequently, and provide immediate transport. If the woman shows signs of shock, position her supine, apply high-flow oxygen, keep her warm, and continue to massage the uterus while providing rapid transport. Gain IV access and give 250-mL boluses of an isotonic crystalloid solution (such as normal saline) as needed to maintain perfusion.

Uterine Inversion

Uterine inversion is a rare but potentially fatal complication of childbirth. In this condition, the placenta fails to detach properly and adheres to the uterine wall when it is expelled. As a result, the uterus literally turns inside out. Uterine inversion usually occurs during the third stage of labor. Its cause is not well understood, but it can result from placing excessive pressure on the uterus during fundal massage or from exerting excess traction on the umbilical cord to hasten delivery of the placenta.

If the inverted uterus prolapses (protrudes outside the vagina), appropriate care includes one attempt at replacement by using the palm of the hand to try to push it back inside the body. If this does not work, cover it with moist dressings and transport while providing supportive care. Never use your fingers to try to replace a prolapsed uterus because this may cause it to tear and result in massive hemorrhage. Administer 100% supplemental oxygen via a nonrebreathing mask. Start two IV lines with normal saline, and titrate fluid administration based on the woman's vital signs. If the placenta is still attached to the uterus, do *not* attempt to remove it. Carefully monitor the patient's vital signs and treat for shock.

Pulmonary Embolism

One of the most common causes of maternal death during childbirth or postpartum is pulmonary embolism. An embolism may form from several sources, but a blood clot arising in the pelvic circulation is a frequent cause. Leakage of amniotic fluid into the maternal circulation (amniotic fluid embolism), a clot arising from deep vein thrombosis (pregnancy-related venous thromboembolism), and an open vessel (air embolism) are examples of potential embolic processes. Should the woman experience sudden dyspnea, tachycardia, or hypotension in the postpartum state, you should suspect pulmonary embolism. The patient may report sudden, sharp chest pain, or abdominal pain, or may experience syncope. Physical examination may reveal nothing unusual except for an increased pulse rate, tachypnea, and hypotension—signs that may be mistaken for shock. Management of a postpartum embolism is the same as management of pulmonary embolism occurring in nonpregnant states: awareness/recognition, high-flow oxygen, and rapid transport.

Spina Bifida

Spina bifida is a developmental defect in which a portion of the spinal cord or meninges may protrude outside of the vertebrae and possibly outside of the body. This is easily seen on the newborn's back and usually occurs in the lower third of the back in the lumbar area. It is important to cover the open area of the spinal cord with a sterile, moist dressing immediately after birth to help prevent

a potentially fatal infection. This treatment will have a positive effect on the newborn's outcome. However, maintenance of body temperature is important when applying moist dressings because the moisture can lower the newborn's body temperature. To prevent this, have someone hold the newborn against their body. Chapter 38, *Patients With Special Challenges*, discusses spina bifida in greater detail.

Neonatal Resuscitation

Physiology

Following birth, the newborn will no longer be connected to the placenta; therefore, it must depend on its own lungs as the only source for oxygen intake and carbon dioxide removal. Over a matter of seconds, the lungs must therefore fill with oxygen and the pulmonary vasculature must dilate to perfuse the alveoli.

In utero (ie, in the pregnant woman's womb), a fetus receives its oxygen from the placenta (**FIGURE 35-18**). The fetal lung is collapsed and filled with fluid, receiving only 10% of the total blood supply. As the fetus is delivered, a rapid series of events needs to occur to enable the newborn to breathe. This process is called **fetal transition**.

The first breath is triggered by mild hypoxia and hypercapnia related to partial occlusion of the umbilical cord during normal delivery. As pulmonary blood vessels continue to dilate and blood levels of oxygen increase, the ductus arteriosus constricts and blood flows preferentially into the lungs, picking up more oxygen to be transported throughout the body. (The ductus arteriosus is a small artery that connects the left pulmonary artery to the aorta and diverts blood away from the fetal lungs while in utero.)

Tactile stimulation and cold stress also promote early breathing. As the newborn's lungs become filled with air, the pulmonary vascular resistance drops, causing more blood to flow to the lungs, picking up oxygen to supply to the body.

Following fetal transition, neonates are now breathing and oxygenating their own blood. As oxygen levels in the blood continue to increase, the neonate's skin turns from cyanotic to pink.

Any event that delays this decline in pulmonary pressure can result in delayed transition, hypoxia, brain injury, and, ultimately, death (**TABLE 35-2**).

FIGURE 35-18 Fetal circulation. **A.** Oxygenated blood from the placenta reaches the fetus through the umbilical vein. Blood returns to the placenta via two umbilical arteries. Shunts (movements of blood from the normal path) occur at the ductus venosus, foramen ovale, and the ductus arteriosus. **B.** Fetal circulation following transition.

Street Smarts

Even during a normal delivery, the time surrounding the birth of a newborn is a very anxious and stressful time. Try to reassure the woman as you work with a distressed newborn. It is best not to separate the newborn from the woman unless you are resuscitating the newborn. Do your best to address concerns and to relieve fears.

Pathophysiology

When certain conditions are present, fetal transition may be delayed. Factors that predispose a newborn to have depressed respiratory function include meconium staining and recent ingestion of drugs or alcohol by the woman.

If fetal distress occurs in utero, the problem is usually caused by compromised blood flow in the placenta or umbilical cord; after delivery, the cause is usually the result of an airway or breathing problem. Clinical findings of fetal distress include the following:

- Persistent cyanosis and/or bradycardia secondary to systemic hypoxia
- Hypotension resulting from decreased coronary perfusion, decreased cardiac output, or blood loss
- Respiratory depression or apnea caused by insufficient oxygen delivery to the brain
- Poor muscle tone from hypoxia and hypercapnia in the muscles

Respiratory distress in the newborn can occur as well and, if untreated, may result in cardiac arrest.

Neonatal Assessment and Initial Steps

Initial steps are aimed at stimulating the newborn to begin spontaneous, effective breathing. They consist of drying, warming, positioning, suctioning, and stimulating the neonate. In most newborns, these initial steps are all that are required to initiate effective breathing.

At birth, a rapid assessment focusing on certain key elements listed in **TABLE 35-3** will determine whether the newborn is in distress. If the answer to any of the questions is no, you must proceed with the initial steps of resuscitation and determine the need for further interventions.

Your initial rapid assessment of the newborn may be done simultaneously with any treatment interventions. Note the time of delivery, and monitor the ABCs. Specifically, assess color, tone, patency of the airway, respiratory rate, respiratory effort, and pulse rate.

Assessing skin color in newborns has several unique features. If the newborn has cyanosis, determine whether it is central or peripheral. This

YOU are the Provider

Part 5

At 1 minute, you calculate the Apgar score as A = 0, P = 2, G = 0, A = 0, R = 0. You aggressively stimulate the newborn while drying, and are relieved to hear her take two gasping breaths followed by a high-pitched cry. At 5 minutes, you note the Apgar score to be 9, taking off only one point for appearance. You note the newborn's color improving and you ask the AEMT who is assisting if the woman can nurse the baby. The AEMT states that the woman is stable and you place the newborn skin-to-skin on the woman's abdomen to allow her to nurse. After ensuring that everyone is safely secured in the back of the ambulance, you instruct your partner to provide smooth transport to Memorial Hospital, which is about 3 miles away. You call in your report to the labor and delivery unit; they confirm they are awaiting your arrival. After you arrive at the hospital you turn the patients over to the labor and delivery staff and complete your patient care reports (one for each patient) while your partner readies the ambulance for the next call.

Newborn Assessment

Recording Time: 5 Minutes After Birth

Respirations	35 breaths/min
Pulse	147 beats/min, regular
Skin	Acrocyanosis
Blood pressure	Not obtained
Oxygen saturation (SpO ₂)	96% on room air
Pupils	Not obtained

9. What are the components of the Apgar score, and what are the average normal scores?

TABLE 35-3 Immediate Assessment of the Newborn

- Is this term gestation?
- Is the newborn breathing or crying?
- Does the newborn have good muscle tone?

© Jones & Bartlett Learning.

difference will help with decision making and treatment. A newborn who has not begun to breathe air will appear cyanotic. This is normal until effective spontaneous breathing occurs, at which time the skin usually “pinks up” rapidly. Many newborns become centrally pink but have blue hands and feet (**acrocyanosis**). This is considered normal in newborns through the first 24 to 48 hours of life and requires no therapy. If the newborn has a normal breathing pattern and a pulse rate of greater than 100 beats/min but maintains **central cyanosis** of the trunk or of the mucous membranes, provide supplemental **free-flow oxygen**. If there is no other warming source available, keep the newborn on the mother’s chest and continue to manage the airway.

Crying is proof of breathing. Normally, a newborn’s respiratory rate will be between 40 and 60 breaths/min. Breathing effort may be slightly irregular in normal newborns. Signs such as gasping, grunting, retractions, or nasal flaring indicate increased work of breathing and respiratory distress. Remember that respiratory distress in the newborn, if untreated, may result in cardiac arrest.

The first step in caring for the newborn is to provide warmth, clear the airway if necessary, and dry and stimulate the newborn. You need to prevent hypothermia. Towels (preferably warmed) should be used for this purpose and should be present immediately following delivery. Thoroughly dry the newborn, particularly the head, which can be a source of substantial body heat loss. Remove any wet blankets, place a cap on the newborn’s head, and place the newborn skin-to-skin with the mother, if possible. When responding to a call for a possible delivery, ensure that the heater in the

**FIGURE 35-19** To avoid airway obstruction, it may be necessary to place a folded towel in between the newborn’s shoulders.

© Jones & Bartlett Learning.

back of the ambulance is turned on, regardless of the time of season. The hypothermic newborn will likely not respond to even the most simple and basic resuscitation measures (such as bag-mask ventilations or blow-by oxygen).

Next, position the newborn on a flat surface and ensure an open airway (sniffing position). Place a towel or blanket under the newborn’s shoulders to help maintain this position (**FIGURE 35-19**).

If there are substantial oral secretions, the airway can be cleared using a bulb syringe or suction catheter. Turn the newborn’s head to the side; suction the mouth before the nose to prevent aspiration. Do not suction vigorously or deeply, as this can induce a vagal response and bradycardia. After the airway is cleared, return the newborn to the sniffing position.

Drying the newborn’s head and body with towels provides adequate stimulation in most cases. However, if the newborn still does not have adequate respirations, additional **tactile stimulation** may be provided *briefly* to stimulate breathing. There are only two acceptable and safe methods for providing tactile stimulation to the newborn: slapping or flicking the soles of the feet and gently rubbing the back, trunk, or extremities. Vigorous stimulation is not helpful and may result in injury to the newborn. *Never* shake a newborn.

Continued use of tactile stimulation in an apneic newborn is wasting precious time. Begin PPV with a bag-mask device and 100% oxygen immediately if brief tactile stimulation fails to initiate breathing or the heart rate is less than 100 beats/min.

Words of Wisdom

In the absence of a warmer, blankets or towels may be warmed by wrapping them around chemical hot packs.

TABLE 35-4 The Apgar Score

Condition	Description	Score
Appearance— skin color	Completely pink	2
	Body pink, extremities blue	1
	Centrally blue, pale	0
Pulse rate	>100	2
	<100, >0	1
	Absent	0
Grimace— irritability	Cries	2
	Grimaces	1
	No response	0
Activity— muscle tone	Active motion	2
	Some flexion of extremities	1
	Limp	0
Respiratory— effort	Strong cry	2
	Slow and irregular	1
	Absent	0

Data from Apgar V. A proposal for a new method of evaluation of the newborn infant. *Curr Res Anesth Analg*. 1953 Jul-Aug;32(4):260-267.

As mentioned earlier, the Apgar score (TABLE 35-4) is the result of an objective method of quantifying the newborn's condition and helps record the condition of the newborn in the first few minutes after birth based on five signs. This score can help you determine the need for specific resuscitation measures and the effectiveness of resuscitation efforts to facilitate the transition from fetus to newborn. The Apgar score is typically recorded at 1 and 5 minutes after birth. If the 5-minute Apgar score is less than 7, the newborn's condition should be reassessed and an additional score assigned every 5 minutes until 20 minutes after birth. If resuscitation is necessary, the Apgar score is assigned after the resuscitation.

Algorithm for Neonatal Resuscitation

Neonatal resuscitation consists of the following sequence of steps:

1. Initial steps in stabilization (provide warmth, clear airway if necessary, dry, stimulate)
2. PPV with oxygen saturation (Spo₂) monitoring
3. Chest compressions if heart rate is below 60 beats/min

4. Consider intubation (call for paramedic backup), continue chest compressions, and coordinate with PPV
5. If the heart rate remains below 60 beats/min, administer IV epinephrine (a paramedic skill) and consider hypovolemia or pneumothorax

The steps for neonatal resuscitation are outlined in FIGURE 35-20. Following the initial steps of resuscitation, the need for and extent of further resuscitation is based on the assessment of three key parameters: respiratory effort, heart rate, and color.

Words of Wisdom

To help remember the initial steps of neonatal resuscitation, remember the saying “Do What Probably Seems Simple,” which stands for:

- **D**o: Drying
- **W**hat: Warming
- **P**robably: Positioning
- **S**eems: Suctioning
- **S**imple: Stimulation

In newborns, bradycardia (heart rate <100 beats/min) is usually the result of hypoxia. Assess the heart rate carefully in a newborn who is not active or who requires PPV. This means either listening to the heart with a stethoscope or palpating the base of the umbilical cord (FIGURE 35-21).

Special Populations

Indications for artificial ventilation of the newborn:

- Apnea
- Pulse rate of less than 100 beats/min
- Persisting central cyanosis despite breathing 100% oxygen

Words of Wisdom

If the newborn does not have adequate respiratory effort and a pulse above 100 beats/min within the first minute after birth, you must begin PPV. Ventilation of the newborn's lungs is the most important and effective treatment during neonatal resuscitation.²³

**FIGURE 35-20** Algorithm for neonatal resuscitation.

Abbreviations: CPAP, continuous positive airway pressure; ETT, endotracheal tube; HR, heart rate; IV, intravenous; LMA, laryngeal mask airway; PPV, positive-pressure ventilation.

FIGURE 35-21 Feel for a pulse at the base of the umbilical cord.

© Jones & Bartlett Learning.

If breathing is not visible (apnea) in the newborn, immediate PPV is required. Room air is preferred when resuscitating term infants, and the addition of supplemental oxygen may not be necessary.²⁴

After 30 seconds of adequate ventilations, assess the heart rate. If the heart rate is at least 100 beats/min and the newborn is breathing adequately, you can stop ventilations and assess the newborn's color. Do not suddenly stop ventilations. Instead, gradually decrease the rate and volume of ventilations to determine whether the newborn will continue to breathe adequately on their own. If not, continue ventilations until the newborn does. You may find that gently stimulating the newborn by flicking the soles of the feet or rubbing the torso will help maintain effective respirations.

Treat heart rates of less than 100 beats/min with PPV, even if respirations are normal. In most newborns with bradycardia, ventilation improves the heart rate to more than 100 beats/min immediately, and no further treatment is necessary.

If the heart rate is less than 60 beats/min, continue ventilation and begin chest compressions. Call for paramedic backup for advanced airway management.

Reassess the newborn after 30 seconds of PPV and chest compressions. If the heart rate is above 60 but below 100 beats/min, discontinue chest compressions and continue ventilations until the heart rate increases to more than 100 beats/min. If the heart rate remains less than 60 beats/min, continue PPV and chest compressions.

If prolonged ventilatory support or certain medications will be needed for the newborn, you should call for paramedic backup.

If central cyanosis is present, administer free-flow oxygen as described later. Continually assess the newborn's color while providing free-flow oxygen. If after 30 seconds of free-flow oxygen central cyanosis persists, perform PPV with 100% oxygen. If the cyanosis dissipates, gradually withdraw the oxygen until you are certain the newborn remains pink on room air. *Never* abruptly withdraw oxygen from any newborn.

Safety

During the birth and resuscitation of the newborn, you must protect yourself from the splashing of blood and other body fluids. Minimum standard precautions include gloves, goggles or a face shield, and a gown.

Airway Management

Free-Flow Oxygen

If a newborn is cyanotic or pale, provide supplemental oxygen. Given that 5 g/dL of deoxygenated hemoglobin is needed before clinical cyanosis becomes apparent, a severely anemic hypoxic newborn will be pale, but not cyanotic. Therefore, provide oxygen to a pale newborn until an accurate oxygen saturation reading can be obtained using a pulse oximeter. Warm and humidify the oxygen if it will be provided for more than a few minutes. If PPV is not indicated (ie, the pulse rate is greater than 100 beats/min and the newborn has adequate respiratory effort), oxygen can initially be delivered through an oxygen mask or via oxygen tubing within your hand that is cupped and held close to the newborn's nose and mouth (**FIGURE 35-22**). The oxygen flow rate should be set at 5 L/min. Apply free-flow oxygen directly to the newborn's face; do not blow oxygen directly into the newborn's eyes.

Bag-Mask Ventilation

Bag-mask ventilation is indicated when a newborn is apneic, has inadequate respiratory effort, or has a pulse rate of less than 100 beats/min (bradycardia).

FIGURE 35-22 Free-flow oxygen can be delivered through an oxygen mask.

© Jones & Bartlett Learning.

after you clear the airway of secretions, relieve obstruction from the tongue, and dry and stimulate the newborn. Signs of respiratory distress that suggest a need for bag-mask ventilation include periodic breathing, intercostal retractions (sucking in between the ribs), nasal flaring, and grunting on expiration.

Recognizing and treating respiratory distress early can reduce mortality and morbidity in newborns. In the field, you will most likely use a self-inflating bag for bag-mask ventilation. If available, always use the infant size (240 mL). Given that the breath size (tidal volume) of a newborn is only 3 to 6 mL/kg, only one-tenth of the bag's volume will be used for each breath, which explains why a larger bag can easily create problems. If a neonatal bag is not available and the newborn is in severe respiratory distress, has apnea, or has bradycardia, you can use a bag designed for adults or older children (750 mL or greater volume) as long as you carefully keep the delivered breath size appropriately small and monitor chest rise to avoid excessive volumes of delivered breaths.

When you are administering bag-mask ventilation with 100% oxygen, the face mask needs to provide an airtight seal, fitting over the newborn's

FIGURE 35-23 Bag-mask ventilation of the newborn. Hold the mask securely to the face with your thumb and index finger. Apply counterpressure under the bony part of the chin with your middle finger.

FIGURE 35-24 The sniffing position.

© Jones & Bartlett Learning.

mouth and nose, and extending down to the chin but not over the eyes (**FIGURE 35-23**). Pressure on the eyes, such as that resulting from deep suctioning, can result in a vagal response and bradycardia. Newborns must have a patent airway, cleared of secretions, with their neck slightly extended in the sniffing position (**FIGURE 35-24**). The first few

FIGURE 35-25 If a pop-off valve is present, occlude it to achieve higher inspiratory pressures.

Courtesy of Rhonda Hunt.

breaths after birth will frequently require higher pressures (possibly approximately 30 mm Hg) because the lungs are not yet expanded and are still full of fluid. To deliver these initial breaths, you may need to manually (cover with your finger) disable the spring-loaded pop-off valve (it is usually set by the manufacturer at 30 to 40 cm H₂O) (**FIGURE 35-25**). Subsequent breaths should be delivered with sufficient pressure to result in visible but not excessive chest rise, with the pop-off valve on.

PPV is successful if you see both sides of the newborn's chest rise and hear breath sounds bilaterally. Use caution when you are ventilating the newborn to avoid inadvertently delivering too much volume, potentially resulting in a pneumothorax.

Special Populations

It may be necessary to bypass the pop-off valve on a bag-mask device during the first few breaths to achieve higher inspiratory pressures in order to clear additional fluid from the alveoli.

In a newborn, it is important to provide the correct timing for ventilation at a rate of 40 to 60 breaths/min because breaths delivered at a higher rate can result in hypocapnia, air trapping, or pneumothorax. To help with the timing, count “breathe—two—three, breathe—two—three” as you ventilate: give a breath on “breathe,” and release on “two—three.”

Continue PPV as long as the pulse rate remains at less than 100 beats/min or the newborn's respiratory effort is ineffective.

The most common reasons for ineffective bag-mask ventilations are inadequate seal of the mask on the face and incorrect head position. Other causes such as copious secretions, pneumothorax, or equipment malfunction need to be considered as well.

Words of Wisdom

Room air is preferred initially in the resuscitation of the term neonate, as hyperoxic injury may occur as a result of the free radicals produced when 100% oxygen is used. The current best practice is to initiate resuscitation with 21% oxygen (room air) and proceed for approximately 90 seconds. After 90 seconds of resuscitation efforts have elapsed with signs of hypoxia still present, providers may use an oxygen blender to administer inspired oxygen concentrations greater than 21%, targeting the desired preductal oxygen saturation for the neonate's age.^{25,26} However, if an oxygen blender is not available, 100% oxygen may be administered. Regardless of the amount of oxygen initiated, the American Academy of Pediatrics recommends using a pulse oximeter to titrate the amount of oxygen delivered.²⁷ Bag-mask ventilation can be initiated with room air while an oxygen source is being secured.

Circulation

Chest Compressions

There are two ways to perform chest compressions in the newborn (**FIGURE 35-26**).

Bag-mask ventilation is performed during a pause after every third compression. Avoid giving a compression and a ventilation simultaneously because one will decrease the effectiveness of the other. You should deliver compressions and ventilations in a 3:1 ratio, for a combined total of 120 “actions” per minute, 90 compressions and 30 ventilations. Keep in mind that adequate ventilation is absolutely critical to the successful resuscitation of the neonate.

Vascular Access

Vascular access is not usually needed in newborns; most problems can be corrected with oxygenation

**A****B**

FIGURE 35-26 Chest compressions in the newborn. **A.** When using the thumb technique, position your thumbs side by side, placed between the xiphoid and an imaginary line drawn between the two nipples. Support the spine by encircling your fingers around the torso. **B.** A single provider may use the two-thumb-encircling-hands technique (preferred) or the two-fingers technique (shown here). When the newborn is large, use two fingers placed between the xiphoid and an imaginary line drawn between the nipples. Use the other hand to support the newborn's head.

© Jones & Bartlett Learning.

**A****B**

FIGURE 35-27 Intravenous access sites in a newborn. **A.** Peripheral veins in the antecubital fossa. **B.** Saphenous veins anterior to the medial malleolus of the ankle.

© Jones & Bartlett Learning.

and ventilation. However, if fluid resuscitation or medications are necessary, you must be able to access the newborn's venous circulation. Establishing peripheral access in a newborn can prove difficult. IV access sites include the peripheral veins in the antecubital fossa and the saphenous veins just anterior to the medial malleolus at the ankle (**FIGURE 35-27**). Intraosseous access can be obtained at the proximal tibia as with older children.

Isotonic crystalloids (such as normal saline or lactated Ringer solution), IV catheters (22 to

24 gauge), and pediatric intraosseous catheters should be included in your supplies.

Though rarely performed at the AEMT level, you may also carry **umbilical vein catheters (UVCs)** if your local protocols allow umbilical vein catheterization. Umbilical catheterization performed by prehospital care providers is a controversial procedure. Although this route of vascular access in experienced hands is effective and quick, the prehospital care provider rarely needs to perform it and complications can occur.

If your EMS system uses UVCs, consider giving all medications and IV fluids this way. The umbilical vein can be catheterized using an umbilical vein line in a newborn by following these steps:

- Clean the cord with alcohol or another antiseptic. Place a sterile tie firmly, but not too tightly, around the base of the cord to control bleeding. Place a sterile drape over the site. Although the line must be placed quickly in a code situation, maintain sterile technique as much as possible.
- Prefill a sterile 3.5F to 5F umbilical vein line catheter (a comparable-size sterile feeding tube can be used in an emergency) with normal saline using a 3-mL syringe. Turn the stopcock to off toward the patient.
- Cut the cord with a scalpel below the clamp placed on the cord at birth approximately 1 to 2 cm from the skin (between the clamp and the cord tie).
- The umbilical vein is a large, thin-walled vessel usually found at the 12-o'clock position, as compared with the two thick-walled umbilical arteries usually found at the 4- and 8-o'clock positions. Insert the catheter into this vein for a distance of 0.75 to 1.5 inches (2 to 4 cm; less in preterm newborns) until blood can be aspirated. If the catheter is advanced into the liver, this may result in irreversible damage. If the catheter is advanced into the heart, dysrhythmias may develop.
- Flush the catheter with 0.5 mL of normal saline and tape it in place.

Do not place the umbilical catheter in too far, but place it to a depth where blood return is first seen. This will help keep the catheter out of the **portal venous system** and avoid complications of certain drugs entering the liver.

Pathophysiology, Assessment, and Management of Specific Conditions

Apnea

Apnea (a respiratory pause greater than or equal to 20 seconds) is common in newborns delivered before 32 weeks of gestation, but is rarely seen in the first 24 hours after delivery, even in premature

newborns. If apnea does not respond to stimulation and further steps such as PPV are not taken, it can result in hypoxemia and bradycardia. Apnea often follows a period of hypoxia or hypothermia. Other causes include maternal or infant narcotic exposure, airway or respiratory muscle weakness, septicemia, prolonged or difficult labor and delivery, gastroesophageal reflux, central nervous system abnormalities including seizures, and metabolic disorders. The pathophysiology of apnea depends on the underlying etiology. Apnea of prematurity is a result of an underdeveloped central nervous system. Gastroesophageal reflux can trigger a vagal response, resulting in apnea. Drug-induced apnea frequently results from direct central nervous system depression. Regardless of the cause, a newborn with apnea needs respiratory support to minimize hypoxic brain damage and other organ damage.

Assessment of an apneic newborn includes obtaining a careful history to elicit possible etiologic risk factors and performing a physical exam that focuses on neurologic signs and symptoms or signs of infection. At birth, it is important to differentiate between **primary apnea** (apnea caused by oxygen deprivation) and **secondary apnea** (a period of gasping respirations, falling pulse rate, and falling blood pressure that occurs after primary apnea in an infant). A newborn who has experienced a relatively short period of hypoxia will have a period of rapid breathing, followed by apnea and bradycardia. At this point, the use of drying and stimulation may cause a resumption of breathing and improvement in the pulse rate. If hypoxia continues during primary apnea, the newborn will gasp and enter secondary apnea. At this point, stimulation alone will not restart the newborn's breathing. Instead, PPV by bag-mask device is required. Follow the steps for neonatal resuscitation discussed earlier in the chapter.

Bradycardia

Bradycardia in a newborn is most frequently a result of inadequate ventilation and often responds to effective PPV. Although increased intracranial pressure in older children can result in bradycardia, neonates have open fontanelles so they rarely present with increased intracranial pressure. Interventions can result in bradycardia as well as vagal stimulation from prolonged suctioning. The morbidity

and mortality of bradycardia are determined by the underlying cause and how quickly it can be corrected.

Heart rate in a newborn is assessed via auscultation or by palpating the base of the umbilical cord. The algorithm for neonatal resuscitation (Figure 35-20) addresses the steps to take when an infant with a heart rate below 100 beats/min is encountered.²⁸ Assess the patency of the airway. If hypoxia continues, there could be persistent bradycardia. Begin chest compressions for a heart rate that is less than 60 beats/min despite at least 30 seconds of effective PPV.²⁹ For persistent bradycardia, call early for paramedic backup for administration of epinephrine. Focus on maintaining normothermia, and provide rapid transport to a facility that has the capacity to treat high-risk neonates.

Words of Wisdom

Bradycardia in a newborn is almost always the result of hypoxia! Provide PPV for a heart rate of less than 100 beats/min.

Hypoglycemia

In the first 1 to 2 hours of life, the blood glucose level of healthy neonates may be 30 mg/dL and increase to more than 45 mg/dL 12 hours after birth.³⁰ In full-term or preterm newborns, hypoglycemia is a blood glucose level of less than 45 mg/dL. This condition represents an imbalance between glucose supply and utilization. Blood glucose levels may be low because of inadequate intake or storage or increased utilization of glucose. Most newborns remain asymptomatic until the glucose level decreases to less than 20 mg/dL for a substantial length of time. Because the brain relies on glucose as its primary fuel, hypoglycemia may result in seizures and severe, permanent brain damage. **TABLE 35-5** lists risk factors for hypoglycemia in the newborn.

The fetus receives glucose from the mother and deposits glycogen in the liver, lung, heart, and skeletal muscle in utero. The newborn then begins to use those glycogen stores to meet glucose needs after birth; most full-term newborns will have sufficient glycogen stores to meet their glucose needs for 8 to 12 hours. Disorders related to decreased glycogen stores (small for gestational age, prematurity,

TABLE 35-5 Hypoglycemia in the Newborn

Risk Factor	Specific Indicators
Disorders of fetal growth and maturity	• Small for gestational age • Smaller of discordant twins (weight difference >25%) • Large for gestational age • Low-birth weight infant (birth weight <5.5 lb [2.5 kg])
Prematurity	• Less than 37 weeks of gestation or less than 5.5 lb (2.5 kg)
Disorders of maternal glucose regulation	• Insulin-dependent diabetes in mother • Gestational diabetes in mother • Morbid obesity in mother
Neonatal conditions with disturbed oxidative metabolism	• Perinatal distress (eg, 5-minute Apgar score <5) • Hypoxemia due to cardiac or lung disease • Shock, hypoperfusion, sepsis, cold stress
Severe anemia	• Pallor (in the absence of hypovolemia)
Congenital anomalies and genetic disorders	• Visible anatomic deformities/abnormalities

© Jones & Bartlett Learning.

postmaturity), including increased use of glucose (hypoxia, hypothermia, sepsis), or increased insulin in the fetus (newborn of a woman with diabetes, large for gestational age) place the newborn at increased risk for hypoglycemia. Frequently, stressed newborns will become hypoglycemic.

Symptoms of hypoglycemia can be quite nonspecific. They may include cyanosis, apnea, irritability, poor sucking or feeding, limpness or floppiness (hypotonia), irregular respirations, eye rolling, hypothermia, and decreased response to stimuli. These symptoms may also be associated with lethargy, tremors, twitching or seizures, and coma. Newborns may also have tachycardia, tachypnea, or vomiting.

In these cases, blood glucose measurement and administration of dextrose (10% solution) may be lifesaving in the field. Check the blood glucose level in all sick newborns (by heel stick), and evaluate the newborn's vital signs. After you establish good oxygenation, ventilation, and circulation, manage the hypoglycemia. Establish IV access as necessary. Medical control personnel may order the administration of a dextrose solution if the newborn's blood glucose level is less than 40 mg/dL. This intervention may be followed by an IV infusion of dextrose based on the newborn's gestational age. Recheck the blood glucose level in about 30 minutes. As always, maintain normal body temperature; hypothermia places additional stress on glucose demand. Warm IV fluids can assist in rewarming the newborn who is hypothermic.

Hypovolemia

Newborns in shock will appear pale and have weak pulses. They may have persistent tachycardia or

bradycardia, and cardiovascular function will often not improve in response to effective ventilation, chest compressions, and cardiac medications. For suspected hypovolemia in the newborn, administer 10 mL/kg of an isotonic crystalloid (such as normal saline or lactated Ringer solution) over 5 to 10 minutes. Although hypovolemia should be corrected fairly quickly, some clinicians are concerned that rapid fluid administration in a newborn may result in intracranial hemorrhage. Reassess the newborn and provide additional fluids as needed.

Words of Wisdom

Treat a hypovolemic newborn as you would an acute trauma patient with life-threatening blood loss who needs blood products. If venous access is needed because of bleeding, transport the newborn immediately and attempt IV or intraosseous access on the way to the hospital.

YOU are the Provider SUMMARY

1. What stage of labor is the patient in?

This patient is presenting in the first stage of labor, which is characterized by the onset of contractions and ends with the cervix being fully effaced and dilated. Because checking for cervical dilation is outside of the AEMT's scope of practice, the end of the first stage of labor is typically determined in the field by the presence of crowning, when the fetus's head is visible at the vaginal opening.

2. Is this patient's medical history important?

This patient has a history that should concern you. With a medical history of eclampsia, gestational diabetes, and delivering her first baby at 29 weeks of gestation, you should be thinking about the possibility of complications with this pregnancy. Because of this information, you should ensure that there is another unit that can respond to your location to assist with multiple patients.

3. Is immediate transport of this patient warranted?

Immediate transport of this patient is not warranted at this point. Even though you and your partner may

feel like you need to get this patient to the hospital quickly so that she does not deliver in your ambulance, you should remain on scene and prepare for delivery. The signs of imminent delivery on this call were the frequency and duration of the woman's contractions, the lack of prenatal care coupled with a history of preterm delivery, and the patient's urge to have a bowel movement. All of these findings point to an imminent delivery.

4. Does this patient need IV access at this point?

Given that this patient has a history of eclampsia and preterm childbirth, it is preferable to obtain IV access sooner rather than later. After labor has progressed and delivery is imminent, there will probably not be enough time to establish IV access in the woman. If IV access can be obtained during the "calm before the storm," it will be one less thing to think about in the middle of the delivery.

5. What are the possible complications if you do not support the baby's head?

After it is obvious that the head is coming out farther with each contraction, you should place your gloved

YOU are the Provider **SUMMARY** *continued*

hand over the emerging bony parts of the head and exert very gentle pressure on it, decreasing the pressure slightly between contractions. This will allow the head to come out smoothly, preventing any tears to the perineum of the woman and possible trauma to the newborn.

6. How do you correct nuchal cord?

A nuchal cord is usually loose and easy to remove from around the newborn's neck; simply slip the cord gently over the newborn's head or shoulder. A nuchal cord that is wound tightly around the neck could cause the newborn to asphyxiate. It must therefore be released from the neck immediately. If you cannot slide the cord over the newborn's head, you must clamp and cut it before the delivery can continue. After you have cut the cord, unwrap it from around the neck. Handle the cord very carefully; it is fragile and easily torn. If it does tear, severe hemorrhage can occur from the woman, newborn, or both.

7. Why is it important to note the time of birth?

Recording time of birth provides you with a starting point from which to time the intervals for Apgar scores. It will ensure that the information is available and accurate for the birth certificate.

8. Why is it important to note whether there was meconium present on delivery?

Meconium causes concern because it can be aspirated into the fetus's lungs, resulting in potentially life-threatening airway issues and possibly sepsis. If meconium is present on birth, you may have to alter the sequence of initial resuscitation and perform more invasive suctioning of the newborn's trachea.

9. What are the components of the Apgar score, and what are the average normal scores?

The Apgar score quantifies a newborn's condition and response to resuscitation. This method is performed 1 and 5 minutes following birth. The Apgar score is not used to determine the need for resuscitation, what interventions are necessary, or when to use them, but rather just to assess the newborn. The components of the Apgar score include **A**ppearance, **P**ulse, **G**rimace or irritability, **A**ctivity or muscle tone, and **R**espiration. Each of the five signs is assigned a value of 2, 1, or 0. The five values are then added. Most newborns will have a score of 7 or 8 at 1 minute and a score of 8 to 10 at 5 minutes.

EMS Patient Care Report (PCR)

Date: 9-12-21	Incident No.: 2257A	Nature of Call: Active labor		Location: I-75 SB MM 135	
Dispatched: 1417	En Route: 1417	At Scene: 1423	Transport: 1458	At Hospital: 1504	In Service: 1529

Patient Information**Age:** 23**Sex:** F**Weight (in kg [lb]):** 83 kg (184 lb)**Allergies:** No known drug allergies**Medications:** None**Past Medical History:** G2P1A0, eclampsia, gestational diabetes mellitus**Chief Complaint:** Labor**Vital Signs**

Narrative				

EMS dispatched to southbound I-75 at mile marker 135 for a woman in labor. On arrival, found male frantically waving us down, states that his girlfriend is going to have a baby, and points to the back of the car, where audible screams can be heard. Patient found supine on rear seat, AOx4, ABCs intact. States her water broke 3 hours ago, and they were on their way to the hospital, but she doesn't think they can make it. States that the contractions are approximately 1 minute apart, lasting 1 minute each. Past medical history of gestational diabetes and eclampsia, no prenatal care this pregnancy. G2P1A0, last pregnancy 29 weeks, vaginal delivery, currently 32 weeks' gestation. Assisted patient to stretcher and placed in back of ambulance. Clothing on lower body removed. 18-gauge IV line right DH established with NS TKO. Patient complains of needing to have a bowel movement, and crowning noted. 2nd ambulance called for additional manpower. Patient prepped for imminent delivery. Baby presents with nuchal cord, easily removed by slipping over head. Cord clamped and cut. Mother appears stable, care of woman turned over to additional crew on scene while newborn is attended. **Female, Time of Birth 1429** 1 minute APGAR was 2 and repeat at 5 minutes was 9. Both patients transported to Memorial Hospital and turned over to L&D staff without incident. See addendum from additional crew for continuing documentation on woman and second PCR for documentation of care of newborn.

End of report

Prep Kit

Ready for Review

- Most births are uneventful and do not require substantial medical intervention.
- When ovulation occurs and a mature egg is released, it travels down the fallopian tubes toward the uterus. If sperm are present, fertilization may occur. The zygote should implant into the lining of the uterus.
- The umbilical cord connects woman and fetus through the placenta. The placenta provides nutrients and eliminates waste from the developing fetus, and acts as a barrier.
- As the fetus grows, the different structures that are recognizable begin to form. All fetal organs have formed by the eighth week of development.
- A baby born at 38 to 42 weeks of gestation is described as term. During the first 28 days of life, a baby is considered a neonate. Between the ages of 1 month and 1 year, a baby is referred to as an infant.
- During pregnancy, the woman's body undergoes many changes to support and protect the developing fetus. Menstruation ceases, the total blood volume increases, the heart rate elevates, blood pressure changes, the respiratory minute volume increases, and gastrointestinal complaints such as morning sickness and heartburn can occur.
- Harmful actions by the pregnant mother (eg, substance misuse) and those who interact with

her (eg, physical abuse) can have significant adverse effects on the developing fetus.

- Emergencies can occur prior to delivery. The most common cause of vaginal bleeding during the first and second trimesters of pregnancy is spontaneous abortion (miscarriage).
- Third-trimester bleeding presents the greatest danger of hemorrhage; a large volume of blood is present within the pregnant woman's body.
- Ectopic pregnancy occurs when the embryo implants in the fallopian tube, ovary, in the abdominal cavity, or the cervix. This is the most life-threatening emergency for the pregnant woman during the first trimester.
- Abruptio placentae and placenta previa are major causes of substantial hemorrhage before delivery. Do *not* try to palpate the abdomen deeply in any woman with third-trimester bleeding; if she has placenta previa, deep palpation may induce heavy bleeding.
- Hypertension may occur during pregnancy. The most common disorder is preeclampsia, an increase in blood pressure after the 20th week of gestation. Preeclampsia can result in cerebral hemorrhage or seizures.
- When a fetus has a different Rh factor than the mother, the antibody may attack fetal red blood cells and create complications such as hemolytic disease.
- Gestational diabetes predisposes the patient to hyperglycemia or hypoglycemia. Uncontrolled diabetes may result in problems during labor and delivery.
- Hyperemesis gravidarum is persistent nausea and vomiting during pregnancy and can result in dehydration and malnutrition. Severe cases require hospitalization.
- Trauma is a serious complicating factor in pregnancy. If a pregnant woman has sustained trauma and is bleeding massively, the maternal circulation will shunt blood away from fetal circulation to maintain maternal homeostasis. Any injury that involves substantial maternal bleeding will threaten the life of the fetus.
- Maintain a high index of suspicion for internal abdominal bleeding in pregnant patients who experienced trauma. Field treatment of pregnant trauma patients focuses on airway management, administration of high-flow oxygen, adequate ventilation, bleeding control, immobilization as needed, administration of intravenous fluids, and transport.
- Use of key obstetric terms such as *gravida* (the number of times a woman has been pregnant) and *para* (the number of times a woman has delivered a viable newborn) will facilitate communication between health care providers.
- Obtain an obstetric history from the patient, asking about any prior pregnancies, complications, prenatal care, and her current condition.
- You will have to determine whether you have time to provide transport to the hospital or attempt delivery in the field. Assist with the delivery of the newborn at the scene when delivery can be expected within a few minutes.
- Management of nondelivery emergencies includes patient positioning, administration of oxygen, intravenous fluid administration depending on the emergency, and emotional support.
- Manage bleeding by positioning the patient in a recumbent position on her left side, administering oxygen, providing rapid transport, providing intravenous fluids, placing trauma pads loosely over the vagina, and considering paramedic backup for pharmacologic treatment.
- There are three stages of labor. The first stage begins with the onset of contractions and ends when the cervix is fully effaced and dilated. The second stage is from the point of full dilation and effacement (crowning) until the newborn is delivered. The third stage is from delivery of the newborn until delivery of the placenta.
- The only times you should place a finger or hand into the vagina are to keep the walls of the vagina from compressing the newborn's airway during a facedown breech presentation or to push the newborn's head away from the umbilical cord if it is prolapsed.

- If you deliver a newborn in the field, remember that your job is to help, guide, and support the newborn during delivery. Always contact medical control for guidance if you have concerns.
- To deliver a newborn, prepare a sterile delivery field. Support the newborn's head as it emerges and feel to see if the cord is wrapped around the newborn's neck. Guide the head and upper body to help deliver the shoulders. Keep the airway open, clamp and cut the cord, and allow the woman to deliver the placenta. Dry the newborn off and wrap the newborn to maintain body heat.
- The Apgar score is designed to measure the success of resuscitation, and should be taken at 1 and 5 minutes following birth.
- After the newborn is delivered and is breathing, you will need to cut the umbilical cord. Clamping of the cord should be delayed 30 seconds after delivery in most vigorous newborns.
- After delivery of the placenta, gently massage the uterine fundus to slow postpartum bleeding. There are many complications that can occur during labor, delivery, and postpartum. Be prepared to assess and manage emergencies by supporting the airway, breathing, and circulation; administering intravenous fluid if needed; and providing rapid transport.
- Complications of labor include preterm labor, postterm pregnancy, fetal distress, and uterine rupture. Uterine rupture can occur after the mother experiences trauma; it causes substantial bleeding that may be internal, external, or both.
- High-risk pregnancy conditions include meconium staining, multiple gestation, cephalopelvic disproportion, intrauterine fetal death, and amniotic fluid embolism.
- Complications of delivery include breech and limb presentations, shoulder dystocia, nuchal cord, and prolapsed umbilical cord. Quickly transport the patient with a limb presentation or prolapsed umbilical cord to the hospital.
- Postpartum complications include excessive bleeding, uterine inversion, pulmonary embolism, and spina bifida.
- After birth, the newborn makes a transition from receiving oxygen through the umbilical cord to breathing on its own. Most newborns breathe spontaneously without any advanced interventions. In a small percentage of births, fetal distress occurs.
- Newborn resuscitation refers to the series of interventions used to stimulate spontaneous breathing. Initial steps of neonatal resuscitation include drying and warming, positioning, suctioning, and stimulating the newborn.
- Three criteria are used to assess the need for further resuscitation in newborns: heart rate, color, and respiratory effort.
- Acrocyanosis is considered normal in newborns in the first 24 to 48 hours of life and requires no therapy. If the newborn has central cyanosis, provide supplemental free-flow oxygen.
- A newborn who is not breathing or whose heart rate is less than 100 beats/min requires immediate positive-pressure ventilation and 100% oxygen. After 30 seconds of adequate ventilation, if the heart rate is at least 100 beats/min and the infant is breathing adequately, you may stop ventilations and assess the newborn's color.
- If a newborn's heart rate is less than 60 beats/min, provide ventilation and begin chest compressions.
- Vascular access is not usually needed for newborns, but if required, intravenous access sites include the peripheral veins in the antecubital fossa and the saphenous vein just anterior to the medial malleolus of the ankle. Umbilical vein catheterization may be allowed in some emergency medical services systems.
- Apnea is a respiratory pause of 20 seconds or longer. If apnea does not respond to stimulation and further steps such as positive-pressure ventilation are not taken, it can result in hypoxemia and bradycardia. A newborn with apnea

needs respiratory support to minimize hypoxic brain damage and other organ damage.

- Bradycardia in a newborn often responds to effective positive-pressure ventilation. Follow the algorithm for neonatal resuscitation when caring for a newborn with bradycardia.

- Signs of hypoglycemia in the newborn can be nonspecific. Measure blood glucose level and evaluate vital signs. If the newborn is hypoglycemic, administer 10% dextrose in water, and keep the infant warm.
- A newborn with hypovolemia may be given an isotonic crystalloid.

Vital Vocabulary

abruptio placentae Premature separation of the placenta from the wall of the uterus.

acrocyanosis A decrease in the amount of oxygen delivered to the extremities. The hands and feet turn blue because of narrowing (constriction) of small arterioles (tiny arteries) toward the end of the arms and legs; can occur at any age; may be benign in infants younger than 2 months.

amniotic fluid The fluid produced by the filtration of maternal and fetal blood through blood vessels in the placenta and by excretion of fetal urine into the amniotic sac.

amniotic fluid embolism An extremely rare, life-threatening condition that occurs when amniotic fluid and fetal cells enter the pregnant woman's pulmonary and circulatory system through the placenta via the umbilical veins, causing an exaggerated allergic response from the woman's body.

amniotic sac The fluid-filled, baglike membrane in which the fetus develops.

Apgar score system A scoring system for assessing the status of a newborn that assigns a number value to each of the five areas of assessment.

birth canal The vagina and cervix.

Braxton-Hicks contractions Irregularly spaced contractions that are more uncomfortable than painful and that do not increase in frequency or otherwise follow the course of true labor contractions; also known as false labor.

breech presentation A type of abnormal delivery in which the buttocks emerge first.

central cyanosis Cyanosis to the newborn's face and trunk; indicates hypoxia.

cervix The lower third, or neck, of the uterus.

chronic hypertension A blood pressure that is equal to or greater than 130/80 mm Hg, which exists prior to pregnancy, occurs before the 20th week of pregnancy, or persists postpartum.

complete abortion The expulsion of all products of conception from the uterus.

crowning The appearance of the newborn's head at the vaginal opening during labor.

ductus arteriosus A small artery that connects the left pulmonary artery to the aorta; diverts blood away from the fetal lungs while in utero.

eclampsia Convulsions (seizures) resulting from severe hypertension in the pregnant woman.

ectopic pregnancy A pregnancy that develops outside the uterus, typically in a fallopian tube.

effacement Thinning and shortening of the cervix; a normal process that occurs as the uterus contracts.

elective abortion Intentional expulsion of the fetus.

embryo The term used to describe the developing infant from fertilization to the end of the eighth week of gestation.

embryonic period The period of gestation between weeks 3 and 8 in which all major organ systems begin to develop.

fallopian tubes The two hollow tubes or ducts that extend from the uterus to the region of the ovary and serve as a passage for the egg and sperm.

fetal alcohol syndrome (FAS) A condition caused by the consumption of alcohol by a pregnant

woman; characterized by growth and physical problems, mental retardation, and a variety of congenital abnormalities in her child.

fetal transition Process through which the fluid in the fetal lungs is replaced with air, the ductus arteriosus constricts, and the neonate begins adequate oxygenation of its own blood.

fetoscope A device used for listening to fetal heart tones.

fetus The developing, unborn infant inside the uterus; the embryo becomes the fetus at the beginning of the ninth week of gestation.

foramen ovale An opening between the two atria that is present in the fetus but usually closes shortly after birth.

free-flow oxygen Oxygen administered via oxygen tube and a cupped hand on the patient's face.

fundus The uppermost part of the uterus, farthest from the cervical opening.

gestation The process of fetal development following fertilization of an egg.

gestational diabetes mellitus The condition in which progesterone (the pregnancy hormone) makes the cells resistant to insulin, resulting in the potential for hypoglycemia or hyperglycemia; typically resolves following delivery.

gestational hypertension High blood pressure that develops after the 20th week of pregnancy in women with previously normal blood pressures, and that resolves spontaneously in the postpartum period; formerly known as pregnancy-induced hypertension.

gestational period The time that it takes for a fetus to develop in utero; normally takes 38 weeks.

grand multipara A term used to describe a woman who has delivered five or more viable infants.

gravid Pregnant.

gravida A term used to describe the number of times a woman has been pregnant.

hyperemesis gravidarum A condition of persistent nausea and vomiting during pregnancy.

imminent abortion A spontaneous abortion that cannot be prevented.

incomplete abortion Expulsion of the fetus that results in some products of conception remaining in the uterus.

infant A young child age 1 month to 1 year.

lightening Movement of the fetus down into the pelvis prior to birth.

limb presentation A delivery in which the presenting part is a single arm, leg, or foot.

meconium The newborn's first bowel movement.

meconium staining The occurrence of a dark-green material in the amniotic fluid that can cause lung disease in the newborn.

menstruation The period in the menstrual cycle of sloughing and discharge of the functional layer of the endometrium; occurs approximately every 28 days.

multigravida A term used to describe a woman who has been pregnant more than once.

multipara A term used to describe a woman who has delivered two or more viable infants.

myoclonus Hyperactive reflexes; occurs during severe preeclampsia.

neonate A newborn age birth to 1 month.

newborn The phase of life from the first few minutes to the first hours after birth.

nuchal cord An umbilical cord that is wrapped around the newborn's neck.

nullipara A term used to describe a woman who has never delivered a viable infant.

ovaries Glands that lie on either side of the pelvic cavity in a woman and produce sex hormones and ova (eggs).

ovum A mature egg released by the ovary during ovulation.

oxytocin A hormone secreted in the pituitary gland that promotes uterine contractions.

para A term used to describe the number of times a woman has delivered a viable (live) infant.

perineum The area of skin between the scrotum and the anus in males, and the vagina and the anus in females.

placenta Tissue attached to the uterine wall that nourishes the fetus through the umbilical cord.

placenta previa A condition in which the placenta develops over and partially or completely covers the cervix.

portal venous system Special venous drainage system that takes blood from the intestines to the liver.

postpartum eclampsia Eclampsia that occurs after a woman has delivered a newborn; can occur up to several weeks after the birth.

preeclampsia A condition during pregnancy characterized by hypertension, protein in the urine, and edema; a precursor to eclampsia.

premature A newborn that delivers before 36 weeks of gestation or weighs less than 5 lb (2.25 kg) at birth.

premature rupture of membranes Rupture of the amniotic sac prior to the onset of labor; increases risk of fetal infection or injury.

preterm Before 36 complete weeks of gestation.

primary apnea Apnea caused by oxygen deprivation; usually corrected with stimulation, such as drying or slapping the newborn's feet; typically preceded by an initial period of rapid breathing.

primigravida A woman's first pregnancy.

primipara A woman who has had only one delivery.

prolapsed umbilical cord A situation in which the umbilical cord comes out of the vagina before the newborn.

rupture of membranes The rupture of the amniotic sac, which normally occurs during labor.

secondary apnea A period of gasping respirations, falling pulse rate, and falling blood pressure that occurs after primary apnea in an infant.

shoulder dystocia A complication of delivery in which there is difficulty delivering the shoulders of a newborn; the shoulder cannot get past the woman's symphysis pubis.

spina bifida A developmental defect in which a portion of the spinal cord or meninges may protrude outside of the vertebrae and possibly even outside of the body, usually at the lower third of the spine in the lumbar area.

spontaneous abortion Delivery of the fetus and placenta by natural causes before 20 weeks of gestation; also known as miscarriage.

supine hypotensive syndrome Low blood pressure resulting from compression of the inferior vena cava by the weight of the gravid uterus when a woman is supine.

tactile stimulation Method of stimulating a newborn to breathe by flicking or slapping the soles of the feet or rubbing the lateral thorax.

term Between 38 and 42 weeks' gestation.

threatened abortion Expulsion of the fetus that is attempting to take place but has not occurred yet; usually occurs in the first trimester.

trimesters Three segments of time, each made up of approximately 3 months, that comprise the length of a pregnancy.

ultrasonography The use of a special device that uses sound waves to determine the location and shape of internal tissues and organs.

umbilical cord The conduit connecting woman to infant via the placenta; contains two arteries and one vein.

umbilical vein catheters (UVCs) Special catheters designed to be inserted into the umbilical cord.

uterine inversion A potentially fatal maternal complication of childbirth in which the placenta fails to detach properly and results in the uterus turning inside out.

uterine rupture Rupture of the uterus, usually by trauma, that can result in life-threatening hemorrhage in the woman and fetus.

uterus The muscular, inverted pear-shaped organ that lies situated between the urinary

bladder and the rectum, where the fetus grows; also called the womb; responsible for contractions during labor.

vagina The muscular tube that forms the lower part of the female reproductive tract; connects

the uterus with the vulva (the external female genitalia); also called the birth canal.

vernix caseosa A white, cheesy substance that covers the fetus.

zygote A fertilized egg.

Chapter 36

Pediatric Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Special Patient Populations

Applies a fundamental knowledge of growth, development, aging, and assessment findings to provide basic and selected advanced emergency care and transportation for a patient with special needs.

Pediatrics

Age-related assessment findings, age-related, and developmental stage-related assessment and treatment modifications for pediatric-specific major diseases and/or emergencies:

- Upper airway obstruction (pp 1743–1747)
- Lower airway reactive disease (pp 1747–1749)
- Respiratory distress/failure/arrest (pp 1741–1742)
- Shock (pp 1756–1757)
- Seizures (pp 1763–1764)
- Sudden infant death syndrome (pp 1782–1784)
- Gastrointestinal disease (p 1766)

Patients With Special Challenges

Recognizing and reporting abuse and neglect (pp 1779–1781 and Chapter 37, *Geriatric Emergencies*) Health care implications of

- Abuse (pp 1779–1781 and Chapter 37, *Geriatric Emergencies*)
- Neglect (p 1780 and Chapter 37, *Geriatric Emergencies*)
- Homelessness (Chapter 38, *Patients With Special Challenges*)
- Poverty (Chapter 38, *Patients With Special Challenges*)
- Bariatrics (Chapter 38, *Patients With Special Challenges*)

- Technology dependent (Chapter 38, *Patients With Special Challenges*)
- Hospice/terminally ill (Chapter 38, *Patients With Special Challenges*)
- Tracheostomy care/dysfunction (Chapter 38, *Patients With Special Challenges*)
- Home care (Chapter 38, *Patients With Special Challenges*)
- Sensory deficit/loss (Chapter 38, *Patients With Special Challenges*)
- Developmental disability (Chapter 38, *Patients With Special Challenges*)

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Special Considerations in Trauma

Recognition and management of trauma in the

- Pregnant patient (Chapter 35, *Obstetrics and Neonatal Care*)
 - Pediatric patient (pp 1771–1776)
 - Geriatric patient (Chapter 37, *Geriatric Emergencies*)
- Pathophysiology, assessment, and management of trauma in the
- Pregnant patient (Chapter 35, *Obstetrics and Neonatal Care*)
 - Pediatric patient (pp 1771–1776)
 - Geriatric patient (Chapter 37, *Geriatric Emergencies*)
 - Cognitively impaired patient (Chapter 38, *Patients With Special Challenges*)

KNOWLEDGE OBJECTIVES

1. Explain some of the challenges inherent in providing emergency care to pediatric patients and why effective communication with both the patient and family members is critical to a successful outcome. (pp 1717–1718)
2. Describe differences in the anatomy, physiology, and pathophysiology of the pediatric patient as compared with the adult patient and their implications for the health care provider, with a focus on the following body systems: respiratory, circulatory, nervous, musculoskeletal, gastrointestinal, and integumentary. (pp 1723–1726)
3. Describe the steps in the primary survey for providing emergency care to a pediatric patient, including the elements of the pediatric assessment triangle (PAT), hands-on ABCDEs, transport decision considerations, and privacy issues. (pp 1728–1736)
4. Discuss the steps in the secondary assessment of a pediatric patient, describing what the advanced emergency medical technician (AEMT) should look for related to different body areas and the method of injury. (pp 1737–1739)
5. Describe the different causes of pediatric respiratory emergencies, the signs and symptoms of increased work of breathing, the difference between respiratory distress and respiratory failure, and the emergency medical care strategies used in the management of each. (pp 1741–1742)
6. List the possible causes of an upper and a lower airway obstruction in a pediatric patient and the steps in the management of foreign body airway obstruction. (pp 1743–1749)
7. List lower airway emergencies in a pediatric patient, including asthma, and possible causes, signs and symptoms, and steps in patient management. (pp 1747–1749)
8. Explain how to determine the correct size of an airway adjunct intended for a pediatric patient during an emergency. (p 1749)
9. List the different oxygen delivery device options that are available for providing oxygen to a pediatric patient, including the indications for the use of each and precautions the AEMT must take to ensure the patient's safety. (pp 1752–1754)
10. Discuss the most common causes of shock (hypoperfusion) in a pediatric patient, its signs and symptoms, and emergency medical management in the field. (pp 1756–1757)
11. Discuss the use of intravenous therapy in pediatric patients, including intraosseous access and fluid resuscitation. (pp 1757–1760)
12. Discuss the most common causes of altered mental status in a pediatric patient, its signs and symptoms, and emergency medical management in the field. (p 1763)
13. List the common causes of seizures in a pediatric patient, the different types of seizures, and their emergency medical management in the field. (pp 1763–1764)
14. List the common causes of meningitis, patient groups who are at the highest risk for contracting it, its signs and symptoms, special precautions, and emergency medical management in the field. (pp 1764–1766)
15. Discuss the types of gastrointestinal disease emergencies that might affect pediatric patients and their emergency medical management. (p 1766)
16. Discuss poisoning in pediatric patients, including common poison sources, signs and symptoms of poisoning, and its emergency medical management. (pp 1766–1767)
17. Discuss dehydration emergencies in pediatric patients, including how to gauge their severity based on key signs and symptoms, and emergency medical management. (pp 1767–1768)
18. Discuss the common causes of a fever emergency in a pediatric patient and the role of the AEMT regarding patient management. (pp 1768–1769)
19. Discuss assessment and management of a child with hypoglycemia. (pp 1769–1770)
20. Discuss assessment and management of a child with hyperglycemia. (p 1770)
21. Discuss the common causes of drowning emergencies in pediatric patients, their signs and symptoms, and emergency medical management. (p 1771)
22. Discuss the common causes of pediatric trauma emergencies and differentiate between injury patterns in adults, infants, and children. (pp 1771–1772)
23. Discuss the significance of burns in pediatric patients, their most common causes, and general guidelines an AEMT should follow when

- assessing patients who have sustained burns. (pp 1776–1777)
24. Explain the four triage categories used in the JumpSTART system for pediatric patients during disaster management. (pp 1778–1779)
 25. Describe child abuse and neglect and its possible indicators, and then describe the medical and legal responsibilities of an AEMT when caring for a pediatric patient who is a possible victim of child abuse. (pp 1779–1781)
 26. Discuss why managing posttraumatic stress is important for all health care professionals. (pp 1781–1782)
 27. Discuss sudden infant death syndrome (SIDS), including its risk factors, patient assessment, and special management considerations related to the death of an infant patient. (pp 1782–1784)
 28. Discuss the responsibilities of the AEMT when communicating with family or loved ones following the death of a child. (pp 1783–1784)

SKILLS OBJECTIVES

1. Demonstrate how to position the airway in a pediatric patient. (p 1732, Skill Drill 36-1)
2. Demonstrate how to palpate the pulse and estimate the capillary refill time in a pediatric patient. (pp 1733, 1734)
3. Demonstrate how to use a length-based resuscitation tape to size equipment appropriately for a pediatric patient. (p 1749)
4. Demonstrate how to insert an oropharyngeal airway in a pediatric patient. (p 1750, Skill Drill 36-2)
5. Demonstrate how to insert a nasopharyngeal airway in a pediatric patient. (p 1751, Skill Drill 36-3)
6. Demonstrate how to administer blow-by oxygen to a pediatric patient. (p 1752)
7. Demonstrate how to apply a nasal cannula to a pediatric patient. (p 1753)
8. Demonstrate how to apply a nonrebreathing mask to a pediatric patient. (p 1753)
9. Demonstrate how to assist ventilation of an infant or child using a bag-mask device. (p 1754)
10. Demonstrate how to perform one-person bag-mask device ventilation on a pediatric patient. (p 1755, Skill Drill 36-4)
11. Demonstrate how to perform two-person bag-mask device ventilation on a pediatric patient. (p 1754)
12. Demonstrate how to obtain intraosseous access in a pediatric patient. (pp 1761–1762, Skill Drill 36-5)
13. Demonstrate how to immobilize a pediatric patient who has been involved in a trauma emergency. (p 1773, Skill Drill 36-6)
14. Demonstrate how to immobilize a pediatric patient who has been involved in a trauma emergency in a car seat. (pp 1774–1775, Skill Drill 36-7)

Introduction

Although pediatric emergencies account for a relatively small percentage (13%) of an emergency medical services (EMS) system's call volume,¹ pediatric mortality is a significant health concern in the United States. Therefore, it is important for you to learn and continually refine your pediatric skills.

It is not uncommon for the prehospital professional to experience anxiety when responding to a call involving a pediatric patient. Assessment and management of infants and children present you with unique challenges. Children differ anatomically, physically, and emotionally from adults. The injuries and illnesses that children sustain, and the

children's responses to them, vary based on age or developmental level. Unlike their adult counterparts, pediatric patients, especially infants and small children, cannot provide you with the historic information that is usually easily obtained from an adult, such as events preceding the incident, what happened, medical history, and where they hurt.

In addition to caring for the sick or injured child, you must also be prepared to deal with parents or caregivers. Many times, they can provide you with the vital information that you need; other times, they may be of little assistance to you.

It is often said that children are not simply small adults, a statement that could not be more true. Unlike adults, children have special needs that

require you to adjust assessment and management strategies accordingly. This chapter discusses those special needs, including anatomic and physiologic differences between children and adults, and the assessment and management of pediatric medical and trauma emergencies.

Communication With the Patient and the Family

It is important to remember that when children are ill or injured, especially those with chronic illnesses, you may have multiple patients to treat rather than just one. Family members, especially the parent or primary caregiver, often need help or support when medical emergencies or problems develop. It is common for parents or caregivers to become angry and demanding when their child is sick or injured. You must realize that this anger is not directed toward you; it is a manifestation of the parents' or caregivers' fear of the situation. A calm parent usually helps to contribute to a calm child. An agitated parent usually means that the child will act the same way. You must remain compassionate, calm, and professional as you deal with pediatric patients and their families.

When possible, allow parents or caregivers to participate in the care of the child. This often helps to calm both the parents and the child, and makes the parents or caregivers feel as if they are making a positive contribution to the situation. If the child is

not critically ill or injured, allow the child to remain on the parent's or caregiver's lap.

Growth and Development

To care for pediatric patients, it is necessary to understand their growth and development stages across the life span. Infancy and toddlerhood have their own specific phases, which are discussed in detail in the next section. The growth and development of infants, toddlers, preschoolers, school-age children, and adolescents was discussed in Chapter 9, *Life Span Development*. Refer to that chapter to familiarize yourself with pediatric stages of development.

The Infant

Infancy is usually defined as the first year of life; the first month after birth is called the neonatal or newborn period.

0 to 2 Months

Infants younger than 2 months spend most of their time sleeping or eating. Sleep accounts for up to 18 hours per day between feeding times and parent or caregiver interactions.² Infants respond mainly to physical stimuli such as light, warmth, hunger, and sound. An infant should be aroused easily from a sleeping state, and it should be considered an emergency if this is not the case.

YOU are the Provider

Part 1

Your ambulance, staffed with an emergency medical responder, an emergency medical technician (EMT), and yourself, is dispatched to 424 N. Cavalier Street for an unresponsive child. On arrival, you are met by an elderly man at the front door who states that the patient is in the back bedroom. You attempt to question him as you proceed to the back of the residence, but he cannot tell you any additional information. In the back bedroom, you find an approximately 5-year-old girl lying supine on the bed; she appears to be unresponsive. You note a middle-aged woman sobbing next to her, who you are able to ascertain is the child's mother. She states that her parents were babysitting and called her about 15 minutes ago, stating that they think the child got into some of their medication. When you ask what type of medication, she states "something for diabetes."

1. What stage of growth and development is this child in, and what are some of the key milestones that you can anticipate seeing?
2. When treating an infant or pediatric patient, what is often the best source of information regarding the current condition?

Infants at this stage have a sucking reflex for feeding. Head control is limited, but infants can turn their heads and focus on faces. Infants have poor thermoregulation, and their heads have a relatively large surface area. These factors predispose them to hypothermia, which is why parents and caregivers will often bundle infants to keep them warm.

Crying is one of the main avenues of expression during this period. Infants may cry when hungry or if they require certain needs to be met. If all obvious needs have been addressed and the infant is still inconsolable, then this could be a sign of significant illness.

Infants are not able to tell the difference between parents and strangers. Their basic needs consist of being kept warm, dry, and fed. They experience the world through their bodies. Being held, cuddled, or rocked soothes the infant. Hearing is also well developed at birth, so calm and reassuring talk is often helpful in soothing the infant.

2 to 6 Months

Infants between ages 2 and 6 months spend more time awake, are more active and social, and can recognize their caregivers. Voluntary smiles and increasing eye contact are common, and at this point in development, infants will begin to roll over. By 4 months of age, infants are able to hold their heads up.

Healthy infants in this age group will have a strong sucking reflex, active extremity movement, and a vigorous cry. They may follow a bright light or toy with their eyes or turn their heads toward a loud sound or the caregiver's voice.

The infant now has an increased awareness of the environment and will use both hands to examine objects and explore the world. As with younger infants, persistent crying and irritability can be an indicator of serious illness. A lack of eye contact in a sick infant can also be a sign of significant illness, depressed mental status, or a delay in development.

6 to 12 Months

Most infants between 6 and 12 months of age can sit unsupported, reach for objects, sleep through the night, and are becoming more mobile—crawling and even walking. Because of this, they are exposed to more physical dangers than before. They become

FIGURE 36-1 Infants are usually not afraid of strangers, but as they reach 6 months to 1 year, they may show signs that they prefer to be with their caregivers.

© Jones & Bartlett Learning. Photographed by Glen E. Ellman.

more aware of their surroundings and also explore their own bodies. During this stage, infants are also teething and tend to pick up anything and place it in their mouths. The risk for foreign body aspirations and poisonings from toxic substances is yet another impending danger. They also begin getting teeth and eating soft foods. Babbling is also common, and by 12 months they learn their first word.

At 6 to 12 months, infants may cry if they are separated from their parents or caregivers (**FIGURE 36-1**). This behavior, called separation anxiety, is common among this age group.

As with younger infants, persistent crying or irritability can be a symptom of serious illness.

Assessment of the Infant

Your assessment of an infant begins with observation of the child's appearance, **work of breathing**, and circulation. These three factors are measured using the **pediatric assessment triangle (PAT)**, which is described in detail later in this chapter.

Because infants cannot communicate their feelings or needs verbally, it is especially important to respect a parent or caregiver's perception that "something is wrong." Nonspecific concerns about a young infant's behavior, feeding, or sleep patterns may be tip-offs to a serious underlying illness or injury. When obvious reasons for crying, such as hunger or needing to be changed, have been addressed, persistent crying can be a sign of significant illness. Although infants spend much

time sleeping, they should arouse easily. Inability to arouse an infant should be considered an emergency. By age 6 months, infants should make eye contact. Lack of eye contact by infants in this age group may be a sign of significant illness or of depressed mental status or delayed development. Those infants approaching age 12 months are at risk for foreign body aspiration and poisoning because of exploration of the environment with their mouths. Crawling and walking also increase exposure to physical dangers.

Consider the best location for performing your primary survey. Although separating a 2-week-old infant from a parent will not cause distress, an older infant in stable condition will be most calm in a parent's arms. Make sure that your hands and stethoscope are warm—a startled, crying infant will be difficult to examine. Be opportunistic with your examination. If the child is quiet, listen to the heart and lungs first, perhaps listening over the clothes before you expose the chest and disturb the infant. If a young infant starts crying, letting the baby suck on a pacifier or gloved finger may quiet the child enough to allow you to complete your assessment. Jangling keys or shining a penlight may distract an older infant long enough for you to finish an examination. Remember to explain each procedure to the parent or caregiver before you perform it.

The Toddler

After infancy, until about 3 years of age, a child is called a **toddler**. Toddlers experience rapid changes in growth and development.

12 to 18 Months

During this period, toddlers begin to walk and to explore their environment. They are able to open doors, drawers, boxes, and bottles. Because they are explorers by nature and are not afraid, injuries in this age group increase. At 12 to 18 months, toddlers begin to imitate the behaviors of older children and parents and may express a desire to dress like mommy or daddy. The toddler knows major body parts when you point to them and may speak four to six words. Because of a lack of molars, toddlers may not be able to fully chew their food before swallowing, leading to an increased risk of food aspiration and choking.

18 to 24 Months

The mind of the toddler develops rapidly. At the beginning of this stage, the toddler may have a vocabulary of 10 to 15 words. By age 2 years, a toddler should be able to pronounce approximately 100 words. When you point to a common object, toddlers should be able to name it. At this stage, toddlers begin to understand cause and effect with such activities as pop-up toys (jack-in-the-box) and turning on and off a light switch. The toddler's balance and gait also improve rapidly during this period. Running and climbing are two skills that develop. At this stage, toddlers tend to cling to their parents and caregivers and often have a special object such as a blanket or teddy bear that comforts them when they are separated (**FIGURE 36-2**).

Assessment of the Toddler

Begin with an assessment of the toddler's interactions with the caregiver, vocalizations, and mobility, measured through the PAT. Persistent crying or irritability can be a symptom of serious illness. Remember that increased mobility in this age group increases their exposure to physical dangers and injury. There is also an increased risk of food aspiration and choking because, given a lack of molars, children may not be able to properly grind up food before swallowing. Examine a toddler in stable condition on the parent's lap and allow them to hold objects that are important to the child. Get down to the child's level, sitting or squatting for the

FIGURE 36-2 Allow a toddler to sit on the parent's or caregiver's lap during your assessment, and use a toy to distract the child.

© Jones & Bartlett Learning. Photographed by Glen E. Ellman.

examination. Begin your assessment with the feet and move toward the head. You may need to be creative to perform a good examination on a toddler with stranger anxiety: use a parent to lift the shirt so that you can assess the respiratory rate, or have the parent press on the abdomen to see if that appears painful. Use play and distraction techniques whenever possible; listening to a doll's chest first may buy you a few minutes of cooperation. Because of their newly found independence, toddlers may be unhappy about being restrained or held for procedures. Offer toddlers limited choices when possible because they like to be in control. If you ask yes or no questions, the answer is likely to be "No!"

Toddlers may have a hard time describing or localizing pain. Pain in the abdomen may be "My tummy hurts," and examination may reveal tenderness throughout the body. This is not because the child is trying to be difficult but because the child cannot tell the difference. The use of visual clues and the Wong-Baker FACES pain scale, discussed later in this chapter, can be helpful with this age group.

Consider performing the more upsetting parts of the examination, such as palpating a tender abdomen or examining an injured extremity, last. Painful procedures make lasting impressions and only increase the difficulty of examining the patient. Be flexible in your approach; some toddlers will not let you complete an orderly full-body examination. Because of developmental changes, children in this age group will generally no longer require shoulder rolls to limit flexion of the neck when ventilating with a bag-mask device or performing advanced airway procedures.

The Preschool-Age Child

Preschool-age children are ages 3 to 6 years (**FIGURE 36-3**). This age group can understand directions, be much more specific in describing their sensations, and identify painful areas when asked. The most rapid increase in language occurs at this stage and toilet training is mastered.

Preschool-age children have a rich imagination, which can make them particularly fearful about pain and change involving their bodies. They are also learning which behaviors are appropriate. Tantrums may occur when they feel they cannot control a situation or its outcomes. The risk of foreign body aspiration continues to be high at this age.

FIGURE 36-3 Preschool-age children have vivid imaginations, so much of the history must still be obtained from the parent or caregiver.

© Jones & Bartlett Learning.

Assessment of the Preschooler

As you perform your assessment beginning with the PAT, take advantage of the child's curiosity and desire to cooperate. If the patient is in medically stable condition, offer to take turns with the child in listening to the heart and lungs. Let the preschooler play with or hold equipment that is safe. Respect modesty and only expose as much as is necessary to complete your examination. To help give the child some sense of control, offer simple choices and tell the child what you are going to do before you do it. Never lie to the patient; after you have lost your pediatric patient's trust, it will be difficult to regain it. Avoid yes or no questions. Set limits on behavior if the child acts out. For the most part, you should be able to talk a preschooler through an orderly full-body examination. Begin your assessment with the feet and move toward the head, similar to assessing a toddler.

Street Smarts

Allowing children to participate in their assessment and care can greatly reduce anxiety. However, you must be careful not to back yourself into a corner. Instead of asking, "Can I listen to your heart?" offer options. Explain, "I need to listen to your heart and feel your tummy. Which would you like for me to do first?" You are giving the child the ability to make decisions while not allowing them to just say, "No!"

FIGURE 36-4 School-age children are more like adults in that they can answer your questions and help take care of themselves.

© Jones & Bartlett Learning.

The School-Age Child

School age refers to children who are ages 6 to 12 years and are beginning to act more like adults. They can think in concrete terms, respond sensibly to direct questions, and help take care of themselves (**FIGURE 36-4**).

School is important at this stage, and concerns about popularity and peer pressure occupy a great deal of time and energy.

Assessment of the School-Age Child

Your assessment begins to be more like an adult assessment; talk to the child, not just the parent or caregiver, while taking the medical history. This will help you gain the patient's trust. At this stage, the child is probably familiar with the process of a physical examination. This may make your job easier or more difficult, depending on whether the child's prior health care experiences have been positive or negative. Begin your assessment at the head and move toward the feet, similar to assessment of an adult.

School-age children can understand the difference between emotional and physical pain. They also have concerns about the meaning of pain. Give them simple explanations about what is causing their pain and what will be done about it. Give the child appropriate choices and control whenever possible, and provide ongoing reassurance and encouragement. Respect the patient's modesty and keep them covered as much as possible during your examination. Games and conversation may distract

these patients. Asking about school will often allow them to warm up to you. Ask them to describe their favorite place, their pets, or their toys. Ask the caregiver's advice in choosing the right distraction. Rewarding the school-age child after a procedure can be helpful in the child's recovery, but only reward a child for completing the procedure.

The Adolescent

An **adolescent** is 12 to 18 years old. They can think abstractly, participate in decision making, and discriminate between what is right and wrong. The adolescent years are when puberty begins and can be difficult. Adolescents are struggling with issues of independence, body image, sexuality, and peer pressure. Although adolescents are still children on an emotional level, this is a time of experimentation and risk-taking behaviors.

Assessment of the Adolescent

The adolescent child should be treated as an adult. During the assessment, you must address the patient. Failure to do so can result in the adolescent feeling left out, thus resulting in you possibly alienating the patient and making it difficult for you to get an accurate assessment or give appropriate treatment. Encourage the patient's questions and involvement. Also, provide accurate information; teens may become alienated and uncooperative if you are suspected of misleading them. Address concerns and fears about the lasting effects of their injuries, especially cosmetic injuries, and reassure them when possible. When communicating, find out what they are interested in, such as sports, books, movies, or friends, and get them talking about this.

When you perform the physical examination, respect the patient's privacy and modesty (**FIGURE 36-5**). If possible, address the adolescent without a caregiver present, especially about sensitive topics such as sexuality, self-endangerment, possible pregnancy, or drug use. Assess the patient's level of pain by observing facial and body expressions as well as by asking questions. If the adolescent's friends are on scene, the adolescent may want them to remain during the assessment. Let the patient have as much control over the situation as is appropriate. Of course, do not let down your guard regarding scene safety.

FIGURE 36-5 Respect the adolescent's privacy at all times; give these patients whatever information they request.

© Jones & Bartlett Learning.

Anatomy, Physiology, and Pathophysiology

There is no other time in our lives that our bodies are growing and changing as fast as during childhood. Newborns quickly change once outside the mother's body. Toddlers learn to walk and talk. School-age children explore the world without thought of consequences. The anatomic and physiologic changes and differences can create difficulties with your assessment of the child if you do not understand them. You need to alter your patient care accordingly.

The Respiratory System

To manage the pediatric airway effectively, you must have a thorough understanding of the anatomic and physiologic differences in the child's airway.

A child's airway is smaller in diameter and shorter in length. The tongue is proportionally larger relative to the size of the mouth and is in a more anterior location in the mouth. The child's tongue also takes up more room in the oropharynx and can easily block the airway. A child's epiglottis is a floppy, narrow, U-shaped structure that is larger than an adult's, relative to the size of the airway, and it extends at a 45° angle into the airway. The larynx is higher (at the C3 to C4 level) and is more anterior. In relation to the adult, whose airway is narrowest at the level of the vocal cords, the narrowest portion of the child's airway is at the level of the cricoid cartilage.

FIGURE 36-6 The anatomy of a child's airway differs from that of an adult's in several ways. The back of the head is larger in a child. The tongue is proportionally larger and is located more anteriorly in the mouth. The trachea is smaller in diameter and more flexible. The airway itself is lower and narrower (funnel-shaped).

© Jones & Bartlett Learning.

The opening to the trachea (glottic opening) is higher (more superior) in the neck and more anterior than in adults, the trachea is smaller in diameter, and the neck and trachea are shorter. Because of the smaller diameter of the trachea in infants, which is about the same diameter as a drinking straw, their airway is easily obstructed by secretions, blood, and swelling. The trachea, which is likened to a piece of corrugated tubing, is easily collapsible in children. Therefore, when they experience respiratory distress, the trachea tends to draw into the neck; this is called **tracheal tugging**.

FIGURE 36-6 illustrates the major differences between pediatric and adult airways.

Infants have little use of their chest muscles to make their chests expand during inspiration; they use the diaphragm (making them belly breathers). Anything that puts pressure on the abdomen of an infant or young child can block the movement of the diaphragm and cause respiratory compromise. Young children also experience muscle fatigue much more quickly than older children, which can lead to respiratory failure if a child has had to breathe hard for long periods.

The tissues of the lungs are more fragile in a child, and the ribs are more cartilaginous, making

them softer and more pliable. In addition, less overlying muscle and fat exist to protect the ribs and vital organs.

Substantial compression injuries to the chest may injure vital intrathoracic organs (such as the heart, lungs, great vessels), often without obvious signs of external injury. When assessing a sick or injured child, expect the ribs to be positioned horizontally. Rib fractures occur less frequently in children but are not uncommon following trauma or abuse.

The fragile **parenchyma** of the child's lungs makes them susceptible to barotrauma (pressure trauma), such as a pneumothorax, as the result of injury or overzealous ventilation. The respiratory muscles in a child are more immature and fatigue more quickly than an adult's; therefore, the child tends to tire more easily as a result of respiratory distress. In addition, because of the thin wall of the child's chest, breath sounds are easily transmitted to all areas of the chest, making it difficult when assessing for a chest injury (such as pneumothorax) or for correct placement of an advanced airway device.

The child's **mediastinum** is more mobile than an adult's. Therefore, you may see a more pronounced mediastinal shift as the result of a tension pneumothorax.

Words of Wisdom

The pediatric patient's ribs and sternum are much more pliable than those of an adult; therefore, you should expect more injuries from blunt trauma to the underlying organs and structures.

Proportionally, tidal volume in children is similar to that in adolescents and adults; however, their metabolic oxygen demand is doubled. In addition, their **functional residual capacity** is smaller, resulting in proportionally smaller oxygen reserves.

An infant needs to breathe faster than an older child (**TABLE 36-1**). The child's lungs will grow and develop better abilities to handle the exchange of oxygen as the child ages. A respiratory rate of 30 to 60 breaths/min is normal for newborns, whereas teenagers are expected to have rates closer to the adult range (12 to 20 breaths/min). Breathing also requires the use of the chest muscles and the diaphragm.

TABLE 36-1 Pediatric Respiratory Rates

Age	Respirations (breaths/min)
Neonate (0 to 1 month)	30 to 60
Infant (1 month to 1 year)	30 to 53
Toddler (1 to 2 years)	22 to 37
Preschool age (3 to 5 years)	20 to 28
School age (6 to 12 years)	18 to 25
Adolescent (12 to 15 years)	12 to 20

Data from American Heart Association (AHA). Vital signs in children. In: AHA. *Pediatric Advanced Life Support*. Dallas, TX: AHA; 2015.

Infants suck air in when they cry. Gastric distention, a more common and significant complication in pediatric patients, can interfere with movement of the diaphragm, resulting in hypoventilation and increased risk of regurgitation with aspiration.

Until the age of approximately 4 to 6 months, infants breathe through their nose. If the nasal passages are blocked by secretions, they may not have the intuition to open their mouths to breathe.

Given the listed anatomic differences, it is important for you to remember the following:

- Keep the **nares** clear in infants younger than 6 months.
- Avoid hyperextension of the child's neck; this may result in reverse hyperflexion and kinking of the trachea and may also displace the tongue posteriorly, creating an airway obstruction.
- Keep the airway clear of all secretions; even a small amount of particulate matter may result in an airway obstruction.
- Use care when managing the child's airway, such as when inserting airway adjuncts; the soft tissues are delicate and susceptible to swelling. In many cases, the child's airway can be maintained by correct positioning, thereby negating the use of airway adjuncts (that is, oral or nasal airways).

You must be aware that infants and children, especially during respiratory distress, are highly susceptible to hypoxia because of their decreased oxygen reserves, increased oxygen demand, and easily fatigued respiratory muscles. Use a larger bag if needed to ventilate a pediatric patient, but use only enough pressure to achieve visible chest rise.

Cardiovascular System

It is important to know the normal pulse ranges when evaluating children (**TABLE 36-2**). Children rely mainly on their heart rate to maintain adequate cardiac output. An infant's heart rate (normally, 90 to 180 beats/min) can be 200 beats/min or more if the body needs to compensate for injury or illness. Because this is the primary method for the child's body to compensate for decreased oxygenation, you must be aware of the normal heart rate ranges when evaluating children.

Children have limited but vigorous cardiac reserves. Proportionally, they have a larger circulating blood volume compared with adults; however, their absolute blood volume is less, approximately 70 mL/kg. The ability of a child to constrict blood vessels (vasoconstriction) provides the ability to keep vital organs well perfused.

Because a child's circulating blood volume is large compared with an adult's, injured children can maintain their blood pressure for longer periods than adults, even though they are still in shock (hypoperfusion). In other words, a proportionally larger volume of blood loss must occur in the child before hypotension develops.

Suspect shock when an infant or child presents with tachycardia. **Bradycardia**, however, usually indicates severe hypoxia and must be managed

aggressively. Remember that hypotension, when it occurs in a child, is an ominous sign and often indicates impending cardiopulmonary arrest.

Words of Wisdom

When you are assessing a sick or injured child, be aware that bradycardia is most often the result of hypoxia; therefore, treatment is aimed at ensuring adequate oxygenation and ventilation. In addition, despite the presence of a normal blood pressure, a child, even more so than an adult, may still be in shock.

Constriction of the blood vessels can be so profound that blood flow to the periphery of the body diminishes. Signs of vasoconstriction can include weak peripheral (radial or pedal) pulses in the extremities; delayed capillary refill (in children younger than 6 years); and pale, cool extremities.

The Nervous System

The nervous system develops continuously throughout childhood. The brain and spinal cord are not as well protected by the developing skull and spinal vertebrae as in adults.

Until the nervous system is fully developed, the neural tissue and vasculature are extremely fragile, easily damaged, and susceptible to bleeding from injury. Because the brain and spinal cord are less well protected than in adults, it takes less force to cause brain and spinal cord injuries in children.

Brain injuries in young children, when they occur, are frequently more devastating.

The subarachnoid space in a child is relatively smaller than that seen in an adult, providing less cushioning effect for the brain. Bruising and damage to the brain may be the result of head momentum such as that seen in "shaken baby syndrome." The pediatric brain also requires nearly twice the cerebral blood flow as the adult brain, making even minor injuries significant. This requirement increases the risk of hypoxia. Head injuries are greatly exacerbated by hypoxia and hypotension, causing ongoing damage.

Spinal cord injuries are less common in pediatric patients; however, injury to the spinal cord may occur without injury to the spinal column itself.

TABLE 36-2 Responsive Pediatric Pulse Rates

Age	Pulse Rate (beats/min)
Neonate (0 to 1 month)	Awake: 100 to 205 Asleep: 90 to 160
Infant (1 month to 1 year)	Awake: 100 to 180 Asleep: 90 to 160
Toddler (1 to 2 years)	Awake: 98 to 140 Asleep: 80 to 120
Preschool age (3 to 5 years)	Awake: 80 to 120 Asleep: 65 to 100
School age (6 to 12 years)	Awake: 75 to 118 Asleep: 58 to 90
Adolescent (12 to 15 years)	Awake: 60 to 100 Asleep: 50 to 90

Data from American Heart Association (AHA). Vital signs in children. In: AHA. *Pediatric Advanced Life Support*. Dallas, TX: AHA; 2015.

Cervical spine injuries are more commonly ligamentous injuries.

Musculoskeletal System

Bones in children are softer and more porous until adolescence. A child's softer bones make an incomplete fracture (**greenstick fracture**) more likely in this population. Treat any sprain or strain as though a fracture exists and immobilize the injury accordingly.

Injury to the **epiphyseal plate** (growth plate or physis) of the bone during its development, or inadvertent puncture of the growth plate during intraosseous (IO) cannulation (discussed later), may result in abnormalities in normal bone growth and development.

The child's head, specifically the **occiput**, is proportionally larger than an adult's. During infancy, the anterior and posterior **fontanelles** are open. The fontanelles are areas where the infant's skull bones have not fused together, thus allowing for compression of the head during the birthing process and for rapid growth of the brain. By the time the child reaches the age of approximately 18 months, both of the fontanelles have closed.

Words of Wisdom

Always assess the fontanelles in the infant:

- Bulging = increased intracranial pressure
- Sunken = dehydration

Because of their proportionally larger heads, infants and children are especially susceptible to head trauma, such as during a fall, in which gravity takes them headfirst. Infants may also experience excessive heat loss as a result of the larger size of the head.

Because of the proportionally larger occiput, special care must be taken when you are positioning the child's airway. In seriously injured children younger than 3 years, place a layer of padding under the shoulders and/or upper back to obtain a neutral position. In seriously ill children younger than 3 years, place a thin layer of padding under the occiput and a thicker layer of padding under the shoulders and/or upper back to obtain a **sniffing position**.³

The fontanelles are an important anatomic landmark when you are assessing a sick or injured infant. Bulging of the fontanelles suggests increased intracranial pressure; sunken fontanelles suggest dehydration. These conditions are discussed later in this chapter.

The Gastrointestinal System

The abdominal musculature in the child is immature and provides less protection to solid, vascular organs such as the spleen and liver, both of which are proportionally larger and more vascular in children. In addition, the abdominal organs are closer to one another.

For these reasons, pediatric patients are at higher risk for splenic and hepatic injuries than adults; even seemingly insignificant forces can cause serious internal injury. Multiple organ injuries are more common.

The Integumentary System

In comparison with adults, infants and children have thinner and more elastic skin, a larger body surface area-to-body mass ratio, and less subcutaneous (fatty) tissue. These factors contribute to the following:

- Increased risk of injury following exposure to temperature extremes.
- Increased risk of hypothermia (can complicate resuscitative efforts) and dehydration.
- Increased severity of burns. Many burns that would ordinarily be classified as minor or moderate in adults are classified as severe in children.

Special Populations

Because of their thinner skin and proportionally larger body surface area-to-body mass ratio, burns are more severe in a child and thus are a leading cause of death in the pediatric age group.

Metabolic Differences

Infants and children have limited stores of glycogen and glucose, which are rapidly depleted as a result of injury or illness. Because it takes glucose to produce energy and energy is required to

maintain body temperature, infants and children are highly susceptible to hypothermia. The risk of hypothermia is further increased because of the child's larger body surface area-to-body mass ratio. When you are assessing and treating a newborn (neonate), you must remain aware that these young infants lack the ability to shiver—one of the body's ways of producing heat.

Significant hypovolemia and electrolyte derangements are also more common in children as a result of severe vomiting and diarrhea.

It is critical to keep the child warm during transport and take measures to prevent the loss of body heat. To conserve body heat, be sure to cover the child's head, which because of its proportionally large size, is a source of substantial heat loss. However, newborns should not be overwarmed because this can worsen their neurologic outcomes.

Pediatric Assessment

As mentioned previously, young children will not be able to provide you with information needed to make treatment decisions (such as medical history, medications). Furthermore, children often cannot tell you where they hurt. Therefore, you must rely

on a parent or caregiver to obtain as much information as you can.

Scene Size-up

Each child and situation is unique; therefore, you may have to modify your assessment of the child based on age. Ensure that you have age-appropriate equipment and review age-appropriate vital signs in anticipation of potential developments. In general, however, you should follow the same general approach to patient assessment for children as you do for adults.

On the way to the scene, prepare for a pediatric scene size-up, pediatric equipment, and the age-appropriate physical assessment. If possible, collect information from dispatch such as the age and sex of the child, the location of the scene, the nature of illness, the mechanism of injury (MOI), and the chief complaint.

As with any EMS call, the scene size-up begins by ensuring that you and your partner have taken the appropriate standard precautions. On arriving at the scene, observe for any hazards or potential hazards that may pose a threat to you, your partner, or the patient. Resist the temptation to hastily

YOU are the Provider

Part 2

Using the PAT, you note the child's appearance to be poor, the work of breathing is substantially decreased, and circulation to the skin is poor based on the finding of cyanosis. Recognizing that this patient is on the verge of respiratory failure, you instruct your partner to insert an appropriate-size oropharyngeal airway and begin bag-mask ventilations with a child-size bag-mask device. After effective assisted ventilations have been established, you quickly place the patient onto the stretcher and into the back of the ambulance. You instruct the mother to sit in the front passenger seat for the transport.

Recording Time: 1 Minute

Appearance	Poor
Level of consciousness	Unresponsive
Airway	Open with oropharyngeal airway
Breathing	4 breaths/min, assisted
Circulation	Cool, clammy, cyanotic

- What is the purpose of the PAT, and what does it assess?
- When should an oropharyngeal airway be inserted in a pediatric patient, and how is it measured?

approach the patient because you know it is a child. Personal safety must always remain your priority.

At a traumatic scene, when the child is unable to communicate because of developmental age or is unresponsive, and caregivers are not present to provide information, assume that the MOI was significant enough to cause head or neck injuries. You must not discount the possibility of child abuse. Conflicting information from the parents or caregivers, bruises or other injuries that are not consistent with the MOI described, or injuries that are not consistent with the child's age and developmental abilities should increase your index of suspicion for abuse. Observe and note the parents' or caregivers' interaction with the child. Do they appear to be appropriately concerned, angry, or indifferent? Does the child seem comforted by their presence or scared by them? Child abuse will be discussed in greater detail later in this chapter.

Street Smarts

Sick or injured children should not be separated from their parents or caregivers unless aggressive resuscitation is needed. The stress produced by separation anxiety can worsen a sick child's condition. If you need to separate the parents or caregiver and child, try to leave them within eyesight and talking distance of one another to minimize the stress of the situation.

Primary Survey

As with the adult population, the objective of the primary survey is to identify and treat immediate or potential life threats. Perform cervical spine immobilization if the MOI is severe. Remember the need to pad under the pediatric patient's head and/or shoulders to facilitate a neutral position for airway management. Always follow local protocols.

When assessing a pediatric patient, use the PAT to form a general impression.

Pediatric Assessment Triangle

The PAT is a structured assessment tool that allows you to rapidly form a general impression of the infant's or child's condition without touching

the child. This 15- to 30-second assessment is conducted prior to the assessment of airway, breathing, circulation, disability, and exposure (ABCDEs), discussed next, and does not require touching the patient. Its intent is to provide a "first glance" assessment to identify the general category of the child's physiologic problem and to establish urgency for treatment and/or transport (**TABLE 36-3**).

The PAT consists of three elements: appearance (muscle tone and mental status), work of breathing, and circulation to the skin (**FIGURE 36-7**). The only equipment required for the PAT are your own eyes and ears; it does not require a stethoscope, blood pressure cuff, cardiac monitor, or pulse oximeter.

TABLE 36-3 Possible Physiologic States Found Using the Pediatric Assessment Triangle

- Respiratory distress
- Respiratory failure
- Cardiovascular shock
- Cardiopulmonary failure or arrest
- Isolated head injury
- Ingestion
- Other primary central nervous system abnormality
- Stable patient

Appearance

The first element of the PAT is the child's appearance. In many cases, this is the most important factor in determining the severity of illness, the need for treatment, and the response to therapy. Appearance reflects the adequacy of ventilation, oxygenation, brain perfusion, body homeostasis, and central nervous system function. The TICLS (pronounced “tickles”) mnemonic highlights the most important features of a child's appearance: Tone, Interactiveness, Consolability, Look or gaze, and Speech or cry (**TABLE 36-4**).

To assess appearance, observe the child from a distance, allowing the child to interact with the caregiver as the child chooses. Delay touching the

patient until you have developed your general impression because the child may become agitated by your touch. Unless a child is unresponsive or critically ill, take your time in assessing general appearance by observation before you begin the hands-on assessment and obtain vital signs.

Words of Wisdom

Identifying an abnormal appearance by using the PAT is a more effective way to detect subtle changes in a child's level of consciousness than by using the AVPU scale (Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive). Many children with mild to moderate illness or injury are “alert” on the AVPU scale, although they may have an abnormal appearance.

TABLE 36-4 Characteristics of Appearance: The TICLS Mnemonic

Characteristics	Features to Look For
Tone	Is the child moving or resisting examination vigorously? Does the child have good muscle tone? Or is the child limp, listless, or flaccid?
Interactiveness	How alert is the child? How readily does a person, object, or sound distract the child or draw the child's attention? Will the child reach for, grasp, and play with a toy or exam instrument, like a penlight or tongue blade? Or is the child uninterested in playing or interacting with the caregiver or AEMT?
Consolability	Can the child be consoled or comforted by the caregiver or the AEMT? Or is the child's crying or agitation unrelieved by gentle reassurance?
Look or gaze	Does the child fix the gaze on a face, or is there a “nobody home,” glassy-eyed stare?
Speech or cry	Is the child's cry strong and spontaneous or weak or high-pitched? Is the content of speech age-appropriate or confused or garbled?

Modified from American Academy of Pediatrics. Pediatric assessment. In: Fuchs S, Klein BL, eds. *Pediatric Education for Prehospital Professionals*. Rev 3rd ed. Burlington, MA: Jones & Bartlett Learning; 2016:6.

Infants or children with a normal level of consciousness will act appropriately for their age, exhibiting good muscle tone and maintaining good eye contact (**FIGURE 36-8**). An abnormal level of consciousness is characterized by age-inappropriate behavior or interactiveness, poor muscle tone, or poor eye contact with the caregiver or with you (**FIGURE 36-9**).

Work of Breathing

Observing a child's work of breathing often provides a better assessment of oxygenation and ventilation status than using auscultation or assessing the

FIGURE 36-8 An infant or child making good eye contact is most likely not critically ill.

© Hemera Technologies/AbleStock.com/Getty Images Plus/Getty Images.

FIGURE 36-9 A limp child who is unable to maintain eye contact may be critically ill or injured.

respiratory rate. The work of breathing reflects the child's attempt to compensate for abnormalities in oxygenation and ventilation and is therefore a good measure for effectiveness of gas exchange. The hands-off assessment of work of breathing includes listening for abnormal airway sounds and looking for signs of increased breathing effort (**TABLE 36-5**).

Increased work of breathing often manifests as **tachypnea**, abnormal airway noise (**grunting** or wheezing), retractions of the intercostal muscles or sternum (**FIGURE 36-10**), or the way the pediatric patient is positioned.

Circulation to the Skin

The goal of rapid circulatory assessment is to determine the adequacy of cardiac output and core perfusion. When cardiac output diminishes, the body responds by shunting circulation from nonessential areas (eg, skin) toward vital organs. Therefore, circulation to the skin reflects the overall status of core circulation. The three characteristics considered when assessing the circulation are pallor, mottling, and cyanosis.

TABLE 36-5 Characteristics of Work of Breathing

Characteristic	Features to Look For
Abnormal airway sounds	Snoring, muffled or hoarse speech, stridor, grunting, or wheezing
Abnormal posturing	Sniffing position, tripod position, refusing to lie down
Accessory muscle use	Retractions of the muscles above the clavicles (supraclavicular)
Retractions	Drawing in of the muscles between the ribs (intercostal retractions) or of the sternum (substernal retractions) during inspiration
Head bobbing	The head lifts and tilts back during inspiration, then moves forward during expiration
Nasal flaring	The nares widen; usually seen during inspiration
Tachypnea	Increased respiratory rate

© Jones & Bartlett Learning.

FIGURE 36-10 Retractions of the intercostal muscles or sternum indicate increased work of breathing.

Pallor of the skin and mucous membranes may be the initial sign of poor circulation or even the only visual sign in a child with compensated shock. It indicates reflex peripheral vasoconstriction that

FIGURE 36-11 Mottling of the skin indicates poor perfusion and is the result of constriction of peripheral blood vessels.

Courtesy Health Resources and Services Administration, Maternal and Child Health Bureau, Emergency Medical Services for Children Program.

is shunting blood toward the core. Pallor may also indicate anemia or hypoxia. Mottling is caused by constriction of peripheral blood vessels and is another sign of poor perfusion (**FIGURE 36-11**).

Cyanosis, a blue discoloration of the skin and mucous membranes, is the most extreme visual indicator of poor perfusion or poor oxygenation. **Acrocyanosis**, blue hands or feet in an infant younger than 2 months, is distinct from cyanosis; it is a normal finding when a young infant is cold. True cyanosis is seen in the skin and mucous membranes and is a late finding of respiratory failure or shock. *Never wait for the development of cyanosis before administering oxygen!*

Stay or Go

On the basis of the findings of the PAT, you will decide if the pediatric patient is stable or requires urgent care. If the pediatric patient is unstable, assess ABCDEs, treat any life threats, and transport the pediatric patient immediately to an appropriate facility. If the pediatric patient is stable, then you have time to continue with the remainder of the patient assessment process.

Hands-On ABCDEs

After forming your general impression of the child's condition using the PAT, perform a hands-on assessment of the child's vital functions—ABCDEs (Airway, Breathing, Circulation, Disability, and Exposure)—and treat any immediate or potential threats to life. If you suspect this is a cardiac arrest,

FIGURE 36-12 Use the head tilt–chin lift maneuver to open the airway of a pediatric patient without trauma.

FIGURE 36-13 Use the jaw-thrust maneuver to open the airway in a pediatric patient with possible spinal injury.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

which is rare, the order is CABDE because chest compressions would be the priority. As previously discussed, your assessment of the child may require modification based on the child's age, but the overall assessment flow is essentially the same as it is for adults.

Airway

If the infant or child is responsive and the airway is open, you can proceed with assessment of respiratory adequacy. However, if the child is unresponsive or has difficulty keeping the airway clear, you must ensure that the airway is properly positioned and that it is clear of mucus, vomitus, blood, and foreign bodies.

If trauma has been ruled out, open the child's airway with the head tilt–chin lift maneuver (**FIGURE 36-12**). If the child has been involved in trauma or trauma is suspected, use the jaw-thrust maneuver to open the airway (**FIGURE 36-13**).

Words of Wisdom

Be gentle when opening the airway of a pediatric patient using the head tilt–chin lift maneuver. You can overextend the neck and actually close off the trachea.

Follow the steps in **SKILL DRILL 36-1** to position the airway in a pediatric patient without trauma.

After the child's airway has been opened, ensure that it is clear of potential obstructions (such as mucus, blood, and foreign bodies). Next, establish whether the child can maintain the airway spontaneously (without the use of airway adjuncts) or whether adjuncts will be necessary to maintain

airway patency. Techniques of airway management will be discussed later in this chapter.

Breathing

The breathing component of the primary survey involves calculating the respiratory rate, auscultating breath sounds, and checking pulse oximetry for oxygen saturation. Assess the child's breathing by noting the degree of air movement at the nose and mouth and determining whether the chest is rising adequately and symmetrically. Assess the respiratory rate and effort with which the pediatric patient is breathing as well.

Place both hands on the pediatric patient's chest to feel for the rise and fall of the chest wall. You will be able to count the actual respiratory rate and assess for symmetry. This assessment maneuver is

Skill Drill 36-1 Positioning the Airway in a Pediatric Patient

Step 1

Place the pediatric patient on a firm surface such as the ground or a short backboard or pediatric immobilization device.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 2

Fold a small towel, about 1 inch (2.5 cm) thick, and place it under the pediatric patient's shoulders and back.

Step 3

Stabilize the forehead to limit movement of the head during transport. Use the head tilt–chin lift maneuver to open the airway.

especially helpful when your pediatric patient requires assisted ventilations with a bag-mask device. In infants, belly breathing is considered adequate because of the soft, pliable bones of the chest and the strong muscular diaphragm.

If the child is responsive and not in need of immediate intervention (such as suctioning or assisted ventilation), assessing respirations is usually easier with the child sitting on the parent or caregiver's lap. Listen for abnormal respiratory sounds and note any signs of increased respiratory effort.

As the child begins to tire, retractions often become weak and ineffective and the accessory muscles become less prominent during breathing. **Bradypnea**, a decrease in the respiratory rate, is an ominous sign and indicates impending respiratory arrest. Do not mistake bradypnea for a sign of improvement; it usually indicates that the child's condition has deteriorated. Therefore, you must be prepared to begin ventilatory assistance.

Circulation

When you are assessing circulation, you must first control any active bleeding. Remember, infants and children can tolerate only small amounts of blood loss before circulatory compromise occurs. Also assess the pulse rate and quality, skin (color, temperature, moisture), **capillary refill time**, and blood pressure.

Pulses may be difficult to palpate if they are weak, extremely fast, or extremely slow. In infants, palpate the brachial pulse or femoral pulse. In children older than 1 year, palpate the carotid pulse (**FIGURE 36-14**). Note the rate and quality of the pulse: Is it weak or strong? Is it normal, slow, or fast? Strong **central pulses** usually indicate that the child is not hypotensive; however, this does not rule out the possibility of compensated shock. Weak or absent peripheral pulses

A

B

C

FIGURE 36-14 A. Palpate the brachial pulse in infants. B. Palpate the femoral pulse as a second choice. C. In children older than 1 year, palpate the carotid pulse.

© Jones & Bartlett Learning.

Special Populations

Blood pressure is just one component of the overall assessment of pediatric patients. Determination of physiologic stability should be based on all data collected from the PAT, physical examination, and initial vital signs. Remember that compensated shock can exist despite adequate blood pressure.

indicate decreased perfusion. Weak central pulses indicate significant hypotension and decompensated shock. The absence of a central pulse (that is, brachial or femoral in infants, carotid in older children) indicates the immediate need for cardiopulmonary resuscitation (CPR).

Tachycardia may be an early sign of hypoxia or shock, but it may also reflect less serious conditions such as fever, anxiety, pain, and excitement. Like respiratory rate and effort, the heart rate should be interpreted within the context of the overall history, PAT, and entire primary survey.

A trend of an increasing or decreasing heart rate may be quite useful information and may suggest worsening hypoxia or shock or improvement after treatment. When hypoxia or shock becomes critical, bradycardia occurs. As with slowing respirations, bradycardia in a child is an ominous sign and often indicates impending cardiopulmonary arrest.

Feel the skin for temperature and moisture while you assess the child's pulse. Is the skin warm and dry or cold and clammy? Estimate the capillary refill time by squeezing the end of a finger or toe for several seconds and then observing the return of blood to the area (**FIGURE 36-15**). Color should return within 2 seconds after you let go. The capillary refill time is used to assess **end-organ perfusion**. It is most reliable in children younger than 6 years; however, factors such as cold temperatures may affect the capillary refill time.

Disability

The assessment of the pediatric patient's level of consciousness can be done using the AVPU scale or the Pediatric Glasgow Coma Scale (**TABLE 36-6**).

Check the responses of each pupil to a direct beam of light. A normal pupil constricts after a light stimulus. Pupillary response may be abnormal in

FIGURE 36-15 Estimate the capillary refill time by squeezing the end of a finger or toe for several seconds until the nail bed blanches. Normal color should return within 2 seconds after you let go.

TABLE 36-6 Pediatric Glasgow Coma Scale

Activity	Score	Infant	Score	Child
Eye opening	4	Open spontaneously	4	Open spontaneously
	3	Open to sound	3	Open to sound
	2	Open to pressure	2	Open to pressure
	1	No response	1	No response
Verbal	5	Coos, babbles	5	Oriented conversation
	4	Irritable cry	4	Confused conversation
	3	Cries	3	Cries
	2	Moans	2	Moans
	1	No response	1	No response
Motor	6	Normal spontaneous movement	6	Obeys verbal commands
	5	Localizes pain or pressure	5	Localizes pain or pressure
	4	Withdraws from pressure	4	Withdraws from pressure
	3	Abnormal flexion	3	Abnormal flexion
	2	Extension	2	Extension
	1	No response	1	No response

^aSome systems use a "Not testable (NT)" score for any element that cannot be tested. Eye opening cannot be tested in a patient whose eyes are closed due to a local factor, such as swelling; verbal response cannot be tested in a patient who has a preexisting factor interfering with communication, such as mutism; and motor response cannot be tested in a patient who has preexisting paralysis or other limiting factor.

Data from *Pediatric Advanced Life Support*, 2015, American Heart Association. © Jones & Bartlett Learning.

Words of Wisdom

You should carry an EMS field guide or place a copy of the modified Glasgow Coma Scale on the wall of the ambulance or in the trauma kit to help you remember how to calculate this difficult formula.

the presence of drugs, ongoing seizures, hypoxia, or brain injury. Note if the pupils are dilated, constricted, reactive, or fixed.

Next, look for symmetric movement of the extremities and note any neurologic motor deficit such as the inability to move the upper or lower extremities, an inability to communicate, weakness, or difficulty walking (gait).

Pain is present with most types of injury and many illnesses. Inadequate treatment of pain has many adverse effects on the pediatric patient and the family. Pain causes significant morbidity and misery for pediatric patients and caregivers and interferes with assessment.

Assessment of pain must take into consideration the developmental age of the patient. The ability to recognize pain will improve as patients become older. For example, crying and agitation in an infant may be the result of hunger or a dirty diaper. Meanwhile, a 3-year-old child can use words to say, “My tummy really hurts.” In children ages 3 years and older, pain scales using pictures of facial expressions (Wong-Baker FACES scale) may be helpful in assessing the level of pain (**FIGURE 36-16**).

Exposure

Proper exposure of the child is necessary to complete the hands-on ABCDEs. The PAT requires that the

caregiver remove part of the pediatric patient’s clothing to allow careful observation of the face, chest wall, and skin. Completing the components requires further exposure, as needed, to fully evaluate physiologic functions, anatomic abnormalities, and unsuspected injuries or rashes. Be careful to avoid heat loss, especially in infants, by covering the patient as soon as possible. Keep the temperature in the ambulance high and use blankets when necessary.

Transport Decision

After you have completed the primary survey using the hands-on ABCDEs and initiated any treatment, you must make a crucial decision: is immediate transport to the hospital indicated, or is additional assessment and treatment required at the scene? If the child is in hemodynamically stable condition, you may elect to perform a secondary assessment at the scene.

However, immediate transport is indicated if the scene is unsafe for the child or if any of the following conditions exist:

- A significant MOI (same MOIs for the adult, in addition to the following):
 - Any fall from a height of greater than twice the pediatric patient’s height, or 10 feet (3 m), especially with a head-first landing
 - Bicycle crash (when not wearing a helmet)
- A history compatible with a serious illness
- A physical abnormality noted during the primary survey
- A potentially serious anatomic abnormality
- Significant pain
- Level of consciousness that is not normal for the pediatric patient, altered mental status, and/or any signs or symptoms of shock

FIGURE 36-16 The Wong-Baker FACES scale.

Wong-Baker FACES Foundation (2017). Wong-Baker FACES® Pain Rating Scale. Retrieved [03/04/2021] with permission from <http://www.WongBakerFACES.org>.

Chapter 26, *Trauma Overview*, discusses significant MOIs in greater detail.

In addition to the preceding factors, you should also consider the following when making a transport decision:

- The type of clinical problem (injury versus illness)
- The expected benefits of advanced life support treatment in the field
- Local EMS system treatment and transport protocols
- Your comfort level
- Transport time to the hospital

If the child's condition is urgent, initiate immediate transport to the closest appropriate facility. Additional assessment and treatment should occur en route to the hospital.

If the child's condition is stable, perform a secondary assessment at the scene, provide additional treatment as needed, and then transport. Remember that unnecessary use of lights and siren may only increase the anxiety level of the child, parent, or caregiver.

Pediatric patients who weigh less than 40 pounds (18 kg) who do not require spinal stabilization should be transported in a car seat as long as the situation allows. Do not use the patient's car seat if there is the potential that it has been damaged. Instead, use a proper immobilization device suited to the size of the child.

To mount a car seat to the stretcher, place the head of the stretcher in an upright position. Place the seat so it is against the back of the stretcher. Secure one of the stretcher straps from the upper portion of the stretcher through the seat belt positions on the seat and strap it tightly to the stretcher. Repeat on the lower portion of the stretcher. Push the car seat into the stretcher tightly and retighten the straps.

To secure a car seat to the captain's chair, follow the seat manufacturer's instructions. Remember that pediatric patients younger than 2 years must be transported in a rear-facing position because of the lack of mature neck muscles.

In some situations, it is not appropriate to secure a pediatric patient in a car seat, for example, if the pediatric patient has to be immobilized on a long backboard or other suitable immobilization device or requires splinting that does not fit in the

seat. If the patient's condition is unstable and requires airway or ventilatory support, the patient should be positioned to maximize the airway and ventilatory requirements. Pediatric patients in cardiopulmonary arrest should likewise not be placed in a car seat but on a device that can be secured to the stretcher. Follow local protocols.

History Taking

Whenever interacting with a child, parents, or caregivers, you should continue to provide emotional support.

When speaking to the child, use age-appropriate terminology; use simple, nonmedical terms when communicating with the parent or caregiver as well. Information exchange will be more accurate and effective if the parent or caregiver understands what you are asking and saying.

Crying and fear are inherent responses of sick or injured children; therefore, you should allow them to express these feelings.

Your approach to the history will depend on the age of the patient. Historical information for an infant, toddler, or preschool-age child will need to be obtained from the parent or caregiver.

Information about sexual activity, the possibility of pregnancy, or the use of illicit drugs or alcohol should be obtained from an adolescent patient in private. Most of these patients will be reluctant to provide this information in the presence of their parents or caregivers. When asking such questions, assure the adolescent that this information is important and is needed to provide the most appropriate care.

Questioning of the parent or child about the immediate illness or injury should be based on the child's chief complaint. This, together with an evaluation of the child's medical history, may provide clues to the underlying illness or injury and other conditions that may exist.

When interviewing the parent or caregiver or older child about the chief complaint, obtain the same pertinent information you would for an adult patient. When obtaining information about the child's medical history, inquire whether the child is currently under the care of a physician, has any chronic illnesses, takes any medications on a regular basis, or has any known drug allergies.

If the parent or caregiver is unable to accompany you to the hospital, obtain a name and phone number so a staff person can call if there are questions. This might be the case when you respond to a day care facility or babysitter's location. Most day care facilities require emergency contact information, medical history, and/or a list of current prescribed medications taken by the child in case of an emergency. Care may be delayed if this information is not discovered early; however, you must never delay care of a critical patient.

Obtaining a SAMPLE history for a pediatric patient is the same as obtaining an adult's. However, the questions should be based on the pediatric patient's age and developmental stage of life.

The OPQRST-I format can help you gather additional information about a patient's history of present illness and current symptoms. As with the SAMPLE history, the questions should be based on the pediatric patient's age and developmental stage of life. OPQRST-I is discussed in Chapter 10, *Patient Assessment*.

Secondary Assessment

As with the adult, a secondary assessment of the child should be performed at the scene, unless the child's condition determines immediate transport. The purpose of the secondary assessment is to obtain additional, specific information about the child's illness or injury.

A full-body exam should be performed on all children with the potential for hidden illness or injury—for example, unresponsive medical patients or trauma patients with a significant MOI. This type of examination may help to identify problems such as distended abdomen or possible fractures that were not as obvious during the primary survey.

Use the DCAP-BTLS mnemonic (Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, and Swelling) to remind you what to assess for a pediatric patient involved in a traumatic event.

A focused assessment is generally performed on patients who have sustained nonsignificant MOIs and on responsive medical patients with a specific complaint. This examination focuses on a certain area or region of the body affected by illness or injury, often determined through the chief complaint.

Circumstances will determine which aspects of the physical examination will be used.

Infants, toddlers, and preschool-age children who do not have apparent life-threatening illness or injuries should be assessed starting at the feet and ending at the head; school-age children and adolescents can be assessed using the head-to-toe approach, as with adults. The extent of the physical examination will depend on the situation and may include the following:

- **Head.** The younger the infant or child, the larger the head is in proportion to the rest of the body, increasing the risk for head injury with deceleration (such as in falls or motor vehicle crashes). Look for bruising, swelling, and hematomas. Substantial blood can be lost between the skull and scalp of a small infant. A tense or bulging fontanelle in an upright, non-crying infant suggests elevated intracranial pressure caused by meningitis, encephalitis, or intracranial bleeding. A sunken fontanelle suggests dehydration.
- **Pupils.** Note the size, equality, and reactivity of the pupils to light. The response of the pupils is a good indication of how well the brain is functioning, particularly when trauma has occurred.
- **Nose.** Young infants prefer to breathe through their nose, so nasal congestion with mucus can cause respiratory distress. Gentle bulb or catheter suction of the nostrils may bring relief.
- **Ears.** Look for any drainage from the ear canals. Leaking blood suggests a skull fracture. Check for bruises behind the ear or Battle sign, a late sign of skull fracture. The presence of pus may indicate an ear infection or perforation of the ear drum.
- **Mouth.** In the trauma patient, look for active bleeding and loose teeth. Note the smell of the breath. Some ingestions are associated with identifiable odors, such as hydrocarbons (eg, gasoline). Acidosis, as in diabetic ketoacidosis (DKA), may impart a fruity smell to the breath.
- **Neck.** Examine the trachea for swelling or bruising. Note if the pediatric patient cannot move the neck and has a high fever. This may indicate that the pediatric patient has bacterial or viral meningitis.

- **Chest.** Examine the chest for penetrating injuries, lacerations, bruises, or rashes. If the pediatric patient is injured, feel the clavicles and every rib for tenderness and/or deformity.
- **Back.** Inspect the back for lacerations, penetrating injuries, bruises, or rashes.
- **Abdomen.** Inspect the abdomen for distention. Gently palpate the abdomen and watch closely for guarding or tensing of the abdominal muscles, which may suggest infection, obstruction, or intra-abdominal injury. Note any tenderness or masses. Look for any seat belt abrasions or bruising.
- **Extremities.** Assess for symmetry. Compare both sides for color, warmth, size of joints, swelling, and tenderness. Put each joint through full range of motion while watching the eyes of the pediatric patient for signs of pain, unless there is obvious deformity of the extremity suggesting a fracture.
- **Capillary refill (in children younger than 6 years).** Normal capillary refill time should occur within 2 seconds. As discussed earlier, assess capillary refill time by blanching the finger or toenail beds; the soles of the feet may also be used. Cold temperatures will increase capillary refill time, making it a less reliable sign.
- **Level of hydration.** Assess skin turgor, noting the presence of **tenting** (in which the skin, when pinched and pulled away slightly from the body, retracts more slowly than normal). In infants, note whether the fontanelles are sunken or flat. Ask the parent or caregiver how many diapers the infant has soiled over the past 24 hours. Determine whether the child is producing tears when crying; note the condition of the mouth. Is the oral mucosa moist or dry?

If the child's condition suggests a cardiac etiology, call early for paramedic backup.

Note that some of the guidelines used to assess adult circulatory status—heart rate and blood pressure—have important limitations in children. First, normal heart rates vary with age in children. Second, blood pressure is usually not assessed in children younger than 3 years; it offers little information about the child's circulatory status and is usually difficult to obtain. In these pediatric patients, assessment of the skin is a better indication of their circulatory status.

It is important to use appropriate-size equipment when you are assessing a pediatric patient's vital signs. To obtain an accurate reading of a pediatric patient's blood pressure, you must use a cuff that covers two-thirds of the pediatric patient's upper arm. A blood pressure cuff that is too small may give you a falsely high reading, whereas a cuff that is too large may give you a falsely low reading.

Words of Wisdom

To estimate the lower limit of normal for the systolic blood pressure in children ages 1 to 10 years, use the following formula: $(\text{Age [in years]} \times 2) + 70 = \text{Systolic blood pressure}$

Respiratory rates may be difficult to interpret. Rapid respiratory rates may simply reflect high fever, anxiety, pain, or excitement. Normal rates, however, may occur in a child who has been breathing rapidly with increased work of breathing for some time and is now becoming tired. Count the respirations for 30 seconds and then double that number. If the patient yawns, sighs, coughs, or talks during the 30-second period, wait a few seconds and begin again. In infants and children younger than 3 years, evaluate respirations by assessing the rise and fall of the abdomen. Assess the pulse rate by counting for at least 1 minute, noting its quality and regularity. Consider taking an **apical pulse** in infants and small children. An apical pulse is obtained by auscultating heart tones over the chest with a stethoscope.

Note that normal vital signs in pediatric patients vary with the age of the child. Remember that your approach to taking vital signs also varies with the age of the child. Be gentle, talk to the child, assess respirations and then the pulse, and assess blood pressure last (**TABLE 36-7**). Warm your stethoscope on your hands or a cloth before placing it on the skin. You may also want to let the child hold the equipment or stethoscope before placing it on the child; this may help to reduce the child's anxiety.

It is recommended that you always obtain the patient's first blood pressure reading manually with a sphygmomanometer (blood pressure cuff) and a stethoscope.

Evaluate pupils in a child using a small penlight. The response of pupils is a good indication of how well the brain is functioning, particularly when

TABLE 36-7 Pediatric Blood Pressure Ranges

Age	Blood Pressure (mm Hg)
Neonate (0 to 1 month)	Systolic: 67 to 84 Diastolic: 35 to 53
Infant (1 month to 1 year)	Systolic: 72 to 104 Diastolic: 37 to 56
Toddler (1 to 2 years)	Systolic: 86 to 106 Diastolic: 42 to 63
Preschool age (3 to 5 years)	Systolic: 89 to 112 Diastolic: 46 to 72
School age (6 to 12 years)	Systolic: 97 to 120 Diastolic: 57 to 80
Adolescent (12 to 15 years)	Systolic: 110 to 131 Diastolic: 64 to 83

trauma has occurred. Be sure to compare the size of the pupils against each other.

In addition, a pulse oximeter is a valuable tool to measure the oxygen saturation in a pediatric patient with respiratory issues (**FIGURE 36-17**). Also assess blood glucose levels with a glucometer.

Reassessment

Reassess the child's condition as determined by the situation; every 15 minutes for a child in stable condition and at least every 5 minutes for a child in unstable condition.

Assessment Pearls

- Build a rapport with small children by making a game out of your assessment. Use a doll or stuffed animal to demonstrate what you intend to do.
- Question parents about the child's normal routine (eg, nap time). Changes in routine may affect behavior and responses.
- Allow children to participate in their care. Have them hold equipment, such as your stethoscope, to hand to you when ready to use.
- Question older children away from their parents or caregivers. They are much more likely to answer honestly when others cannot hear their responses.
- If the infant is facing away from you, take advantage of the opportunity to assess breathing and heart rate via auscultation of the back. This approach will be more accurate than assessing the rates of an infant who is upset by the sight of a stranger.
- Be alert for subtle signs of shock and treat aggressively. Progression of shock is not as obvious in children as in adults, because children initially compensate well and then decompensate rapidly.
- Know your pediatric drug doses or keep a field guide readily available!

The physiologic safeguards in infants and children can decompensate with alarming unpredictability; therefore, continually monitor respiratory effort, skin color and condition, and level of consciousness or interactivity. Frequently reassess oxygen saturation and vital signs. Repeat the primary survey and adjust your treatment accordingly.

When you are providing interventions for a pediatric patient, you should always consider getting help from the patient's parent or caregiver during these procedures. This is especially helpful during painful procedures (such as intravenous [IV] therapy). It facilitates your ability to assess and treat the child, it calms the child, and it helps to alleviate anxiety in the parent or caregiver. You should build a trusting environment and attempt to not frighten the pediatric patient who is already in a state of stress. Pediatric patients can sense fear from a provider and may not be willing to let you render care.

Communicate with the hospital on your findings and the interventions you used to improve the pediatric patient's condition. Be sure that all of this information is documented and given to

Documentation and Communication

Perform frequent reassessment of serial vital signs, and record them on your documentation form. By recording each set of vital signs, you can visualize trends and transfer important information to the accepting physicians.

emergency department (ED) personnel. Remember, a patient care report is a legal document and you may be called to answer questions about this report for years to come.

Pediatric Emergency Medications

In your care for pediatric patients, you may sometimes administer medications. **TABLE 36-8** lists

TABLE 36-8 Pediatric Emergency Medications

Drug	Pediatric Dosage	Route
Albuterol (Proventil, Ventolin)	<20 kg: 1.25 mg/dose via handheld nebulizer or mask over 20 min. >20 kg: 2.5 mg/dose via handheld nebulizer or mask over 20 min. Repeat once in 20 min.	Inhalation
D ₂₅	Age 1 year and older: 0.5–1 g/kg of D ₂₅ via slow IV/IO push. May be repeated as necessary. Neonates and infants: 200–500 mg/kg slow IV push. May be repeated as necessary. Maximum concentration of 12.5% (vasculature extremely sensitive to high concentrations).	IV
Dextrose 10%	2.5–5.0 mL/kg If needed, it can be administered via infusion, likely with a 10% dextrose solution.	IV
EPINEPHrine ^a (Adrenalin)	Anaphylaxis and asthma: 0.01 mg/kg (0.01 mL/kg) of 1 mg/mL (1:1,000) solution subcutaneous/IM. Maximum dosage of 0.3 mg. Can be repeated every 5 minutes.	Subcutaneous/ IM
Glucagon	Hypoglycemia: 1 mg IM/IN for body weight of 20 kg or greater (or age 5 years or more); 0.5 mg IM/IN if less than 20 kg or younger than 5 years.	IM
Naloxone hydrochloride (Narcan)	0.1 mg/kg IV/IO/IM for infants and children from birth to 5 years of age or 20 kg of body weight. Children older than 5 years of age or weighing more than 20 kg may be given 2.0 mg. These doses may be repeated every 2 minutes as needed to maintain opiate reversal to a maximum dose of 2 mg.	IV
Nitrous oxide	Invert the cylinder several times and have the patient inhale deeply through the demand valve or the mouthpiece. Titrate to effect.	Inhalation
Oxygen	Cardiac arrest and carbon monoxide poisoning 100%. Hypoxemia 12–15 L/min via nonrebreathing mask. Be prepared to provide positive-pressure ventilations for those with inadequate respiratory effort.	Inhalation
Activated charcoal	0.5–1 g/kg PO Typical dose is 12.5–25 g up to 1 year of age and 25–50 g for ages 1–12 years.	Oral

medications in your scope of practice at the advanced emergency medical technician (AEMT) level, for reference as you read about assessment and management of specific emergencies throughout the rest of this chapter.

Assessment and Management of Respiratory Emergencies

Infants have a limited ability to compensate for respiratory insults and often expend huge amounts of energy to breathe. At times, infants are intubated to take over the work of breathing even when adequate physiologic parameters are being maintained. In older children, increasing compensatory skills develop, and juvenile patients with asthma can sometimes compensate for days, with adequate oxygen saturation, before tiring out and literally dying of fatigue.

Many infants and children with respiratory conditions have respiratory distress (difficulty breathing), some have respiratory failure (which invariably leads to decompensation), and a few are in respiratory arrest. If the child in respiratory arrest can be resuscitated before cardiac arrest occurs, survival with a return to full function is likely. Any respiratory compromise in children must be monitored closely and the child transported to the closest ED. If a pediatric-specific ED is available, consult medical direction or your local transport protocols for advice.

When you are faced with a respiratory emergency, the first step is to determine the severity of the disease: is the patient in respiratory distress, respiratory failure, or respiratory arrest? Keep the anatomic and physiologic respiratory differences in mind as you approach the child.

Respiratory distress entails increased work of breathing to maintain oxygenation and/or ventilation; that is, it is a compensated state in which increased work of breathing results in adequate pulmonary gas exchange. Signs of respiratory distress—which is classified as mild, moderate, or severe—include the following:

- Pallor or mottled color
- Irritability, anxiety, restlessness
- Respiratory rate faster than normal for age
- Retractions (suprasternal, intercostal, subcostal)
- Abdominal breathing

- Nasal flaring
- Inspiratory stridor
- Grunting
- Mild tachycardia

A patient experiencing **respiratory failure** can no longer compensate for the underlying pathologic or anatomic problem by increased work of breathing, so hypoxia and/or carbon dioxide retention occur. Signs of respiratory failure may include decreased or absent retractions caused by fatigue of the chest wall muscles, altered mental status caused by inadequate oxygenation and ventilation of the brain, and an abnormally low respiratory rate (**TABLE 36-9**). Respiratory failure is a decompensated state, requiring urgent intervention to

Special Populations

Initiate aggressive airway management and ventilatory support with a bag-mask device and supplemental oxygen as soon as possible for a child with respiratory failure.

TABLE 36-9 Signs of Impending Respiratory Failure

Assess	Sign
Mental status	Agitation, restlessness, confusion, lethargy (VPU components of the AVPU scale)
Skin color	Central cyanosis despite oxygen administration, pallor
Respiratory rate	Tachypnea → bradypnea → apnea
Respiratory effort	Severe retractions and accessory muscle use, nasal flaring, grunting, paradoxical abdominal motion, tripod positioning
Auscultation	Stridor, wheezing, crackles, or diminished air movement
Blood oxygen saturation	Low despite supplemental oxygen administration
Pulse rate	Tachycardia → bradycardia

Abbreviation: AVPU, Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive

© Jones & Bartlett Learning.

ensure adequate oxygenation and ventilation and prevent respiratory or cardiopulmonary arrest. Do not be afraid to assist ventilations at this point if you judge the tidal volume or respiratory effort to be inadequate.

Respiratory arrest means the patient is not breathing spontaneously. Administer immediate bag-mask ventilation with supplemental oxygen to prevent progression to cardiopulmonary arrest. Resuscitation of a child from respiratory arrest is often successful, whereas resuscitation of a child in cardiopulmonary arrest may or may not be.

Your determination of whether the patient is in respiratory distress, respiratory failure, or respiratory arrest will drive your next steps by indicating the urgency for treatment and transport. You can obtain the SAMPLE history at the scene or during transport, depending on the patient's stability. **TABLE 36-10** lists key components to ask about during a respiratory emergency.

TABLE 36-10 SAMPLE Components for Pediatric Respiratory Emergencies

Component	Features
Signs and symptoms	Shortness of breath, hoarseness, stridor, wheezing, cough, chest pain, choking, rash/hives, cyanosis
Allergies	Known medication or food allergies; smoke exposure
Medications	Names and doses of ongoing medications; recent use of corticosteroids
Past medical history	History of asthma, chronic lung disease, heart problems, prematurity; prior hospitalizations and intubation for breathing problems; history of choking or anaphylaxis; immunizations
Last oral intake	Timing of last food, including bottle or breastfeeding
Events leading to illness or injury	Fever history or recent illness; history of injury to chest; history of choking on food or object

© Jones & Bartlett Learning.

Most pediatric patients with a primary respiratory issue will have respiratory distress and require only supportive care. Allow the child to assume a position of comfort and provide supplemental oxygen. The choice of oxygen delivery method will depend on the severity of illness and the child's developmental level. Young children may become agitated by a nasal cannula or face mask. Because crying and thrashing increase metabolic demands and oxygen consumption, you must weigh the benefits of this therapy against the potential cost. Allowing a caregiver to deliver **blow-by oxygen** to a calm toddler may be your best choice if the child does not show signs of respiratory failure.

Special Populations

Respiratory distress, respiratory failure, and respiratory arrest exist along a continuum. Intervene early and aggressively to prevent progression to respiratory arrest in pediatric patients.

As a child becomes fatigued, respiratory distress may progress to respiratory failure. As part of your reassessment, electronically monitor the patient's pulse rate, respiratory rate, and oxygen saturation level. A significant change or trend in any of these variables requires prompt attention. You should also perform frequent reassessment to evaluate the effects of your treatment.

Consider the following when caring for a child with a respiratory emergency:⁴

- Give supplemental oxygen; escalate from a nasal cannula to a simple face mask to a non-rebreathing mask or positive-pressure ventilation (PPV) as needed to maintain normal oxygenation.
- Perform electrocardiographic monitoring if there are no signs of clinical improvement after treating respiratory distress.
- Establish IV access if you have clinical concerns about dehydration or if you anticipate the need to administer IV medications.
- The child's airway should be managed in the least invasive way possible. Supraglottic airway devices and intubation should be performed only if bag-mask ventilation fails.

Upper Airway Emergencies

Airway obstructions can be caused by foreign objects, infection, or disease. For example, infections, such as pneumonia, croup, epiglottitis, and bacterial tracheitis, should be considered as a possible cause of airway obstruction if a pediatric patient has congestion, fever, drooling, and cold symptoms.

Signs and symptoms that are frequently associated with an upper airway obstruction include decreased or absent breath sounds and stridor. Stridor, a high-pitched noise heard mainly on inspiration, is usually caused by swelling of the area surrounding the vocal cords or upper airway obstruction. In pediatric patients with croup, their cough sounds like the bark of a seal.

Foreign Body Aspiration or Obstruction

Children, especially those younger than 5 years, can (and do) obstruct their airway with any object

that they can fit into their mouth (such as hot dogs, balloons, grapes, or coins) (**FIGURE 36-18**). In cases of trauma, a child's teeth may have been dislodged into the airway. Blood, vomitus, or other secretions can also cause mild or severe airway obstruction.

FIGURE 36-18 Any number of objects can obstruct a child's airway. Some of the more common ones include batteries, coins, toys, buttons, and candy.

YOU are the Provider

Part 3

You contact dispatch to request a paramedic intercept and are informed that there are no units available. You obtain a complete set of vital signs, including a capillary blood glucose level, which reads 26 mg/dL. Knowing that this value is extremely low, you retrieve your supplies and prepare to cannulate a vein. On the basis of the patient's size and the need for IV glucose, you select the largest-size catheter that you believe you can insert on the first attempt, a 22-gauge catheter. Following local protocols, you place a Volutrol onto your bag of normal saline (NS) and fill the chamber to 100 mL. You successfully establish IV access to the patient's left wrist on the first attempt. After ensuring that the line is patent and secure, you prepare your IV glucose solution. You direct your partner to initiate rapid transport to the closest hospital, which is approximately 18 minutes away. Once en route, you ensure that your other partner is continuing assisted ventilations with the bag-mask device and that there is good chest rise and fall.

Recording Time: 8 Minutes

Respirations	20 breaths/min, assisted
Pulse	155 beats/min, regular
Skin	Warm and dry
Blood pressure	Unable to obtain
Oxygen saturation (Spo₂)	99% on 15 L/min
Pupils	Equal and sluggish

- 5.** What are normal vital signs for a patient of this age?
- 6.** What is the purpose of a Volutrol?
- 7.** How should the glucose be prepared?

FIGURE 36-19 If a pediatric patient has a partial airway obstruction, do not intervene except to give supplemental oxygen. Allow the child to remain in whatever position is most comfortable during transport.

© Jones & Bartlett Learning. Photographed by Glen E. Ellman.

Treatment of the pediatric patient with an airway obstruction must begin immediately. If the patient is responsive and coughing forcefully and you know for sure that there is a foreign body in the airway (that is, if someone actually saw the object go into the child's mouth) encourage the child to cough to clear the airway. If the material in the airway does not completely block the flow of air, the pediatric patient may be able to breathe adequately without any intervention. In such cases, do not intervene except to provide supplemental oxygen (**FIGURE 36-19**). Allow the pediatric patient to remain in whatever position is most comfortable, and monitor the patient's condition during transport.

Words of Wisdom

Infants or children presenting with acute respiratory distress in the absence of fever should be suspected of having a foreign body airway obstruction.

If you see signs of a severe airway obstruction, however, you must attempt to clear the airway immediately. The signs include the following:

- Ineffective cough (no sound)
- Inability to speak or cry
- Increasing respiratory difficulty, with stridor
- Cyanosis
- Loss of consciousness

If an infant is responsive with a complete airway obstruction, perform up to five back blows followed by five chest thrusts. First, position the infant facedown on your forearm. Support the infant's jaw and head with your hand. Next, use the heel of your other hand to slap the back forcefully five times (between the shoulder blades). If the airway does not clear, flip the infant onto the back, using your hand to support the head. Perform up to five chest thrusts in the same manner you would provide chest compressions for CPR. Repeat the process until the obstruction clears or until the infant becomes unresponsive.

If a child (older than 1 year) is responsive with a complete airway obstruction, perform abdominal thrusts (Heimlich maneuver). Continue until the obstruction clears or until the child becomes unresponsive.

If there is reason to believe that an unresponsive child has a foreign body obstruction and there are no suspected spinal injuries, open the airway using the head tilt–chin lift maneuver and look inside the mouth to see whether the obstructing object is visible. If the object is visible, try to remove it using a finger sweep motion. Never use finger sweeps if you cannot see the object because you may push it farther into the airway.

Chest compressions are recommended to relieve a severe airway obstruction in an unresponsive pediatric patient. Chest compressions increase the pressure in the chest, creating an artificial cough that may force a foreign body from the airway. Chapter 15, *BLS Resuscitation*, covers clearing a foreign body obstruction in an infant and child in detail.

Anaphylaxis

Anaphylaxis is a potentially life-threatening allergic reaction, triggered by exposure to an antigen (foreign protein). Food—especially nuts, shellfish, eggs, and milk—and bee stings are among the most common causes, although anaphylaxis to antibiotics and other medications can occur as well. Exposure to the antigen stimulates the release of histamine and other vasoactive chemical mediators from white blood cells, leading to multiple organ system involvement. Onset of symptoms generally occurs immediately after the exposure and may include hives, respiratory distress, circulatory compromise,

and gastrointestinal symptoms (vomiting, diarrhea, abdominal pain). See Chapter 22, *Immunologic Emergencies*, for more information about the sequence of events in anaphylaxis.

Although a child with mild anaphylaxis may experience only hives and some wheezing, a child with severe anaphylaxis may be in respiratory failure and shock when you arrive. The PAT may reveal an anxious child (many adults describe a sense of impending doom at the onset of anaphylaxis). With severe anaphylaxis, the child may be unresponsive as a result of respiratory failure and shock. The child may have increased work of breathing due to upper airway edema or bronchospasm and poor circulation. The primary survey will usually reveal hives, with other findings potentially including swelling of the lips and oral mucosa, stridor and/or wheezing, and diminished pulses. If the child has a known allergy, the SAMPLE history may reveal recent contact with or ingestion of the potentially offending agent (including consumption of prepared foods containing traces of eggs, nuts, and milk at day care or school).

The “gold standard” treatment for anaphylaxis is epinephrine. Epinephrine’s alpha agonist effect decreases airway edema by **vasoconstriction** and improves circulation by increasing peripheral vascular resistance. Its beta agonist effect causes bronchodilation, resulting in improved oxygenation and ventilation. Epinephrine should be given by the intramuscular (IM) route at a dose of 0.01 mg/kg of the 1 mg/mL (1:1,000) solution, to a maximum dose of 0.3 mg. This dose may be repeated as necessary every 5 minutes. In addition to epinephrine, treatment of anaphylaxis should include supplemental oxygen, fluid resuscitation for shock, and bronchodilators for wheezing. Diphenhydramine (Benadryl) is also indicated for its antihistamine effect, but is not within the scope of practice of the AEMT.

Many children with a history of anaphylaxis will have been treated with IM epinephrine by a caregiver before EMS activation. Given the short half-life of this drug, the child should be transported, even if asymptomatic on your arrival.

Croup

Croup (laryngotracheobronchitis) is an infection of the upper airway below the level of the vocal cords, usually caused by a virus. The parainfluenza virus

is the pathogen most commonly responsible for croup, but respiratory syncytial virus (RSV), influenza, and adenovirus have also been implicated. The virus is transmitted by respiratory secretions. Croup primarily affects children 6 months to 3 years of age, with most cases occurring in the fall and winter months.⁵ The virus has an affinity for the subglottic space, the narrowest part of the pediatric airway, and causes edema and progressive airway obstruction. Turbulent airflow through the narrowed subglottic airway causes the hallmark sign of croup: stridor.

Words of Wisdom

RSV is highly contagious and spread through droplets when the pediatric patient coughs or sneezes. RSV is more common in premature infants and results in copious secretions that may require suctioning. The virus can also survive on surfaces, including hands and clothing—including on yours. The infection tends to spread rapidly through schools and in child care centers. RSV is discussed in Chapter 17, *Respiratory Emergencies*.

Most cases of croup are mild. EMS may be called when the symptoms come on abruptly, often in the middle of the night, or if symptoms cause moderate to severe respiratory distress. The PAT for a child with croup will typically reveal an alert infant or toddler who has audible stridor with activity or agitation, a barking cough, some increased work of breathing, and normal skin color. If a child with a history compatible with croup is sleepy or obtunded or has significant respiratory distress or cyanosis, be concerned about critical airway obstruction. On your primary survey, breath sounds will likely be clear over the lung fields, although you may hear stridor (originating at the level of the subglottic space). Because the pathophysiology of croup largely involves the upper airway, hypoxia is uncommon, and its presence should alert you to critical obstruction and the need for immediate treatment. The SAMPLE history usually reveals several days of cold symptoms and low-grade fever, followed by the onset of a barking cough, stridor, and trouble breathing. The cough and respiratory distress are often worse at night.

The initial management of croup is the same as for most respiratory emergencies. Allow the child to assume a position of comfort and avoid agitating the child. The use of humidified oxygen may be beneficial.^{6,7} For patients with stridor at rest, moderate to severe respiratory distress, poor air exchange, hypoxia, or altered appearance, nebulized epinephrine is the treatment of choice. It works by causing vasoconstriction and decreasing upper airway edema. Call early for paramedic backup if nebulized epinephrine is needed.

In the case of croup and respiratory failure, assisted ventilation with bag-mask ventilation will often succeed in overcoming the upper airway obstruction. Advanced airway placement is rarely needed in croup. Children requiring medication or assisted ventilation need to be transported immediately to an appropriate treatment facility.

Special Populations

Cystic fibrosis, a genetic disease that primarily affects the respiratory and digestive systems, chronically produces copious amounts of thick mucus in the respiratory and digestive tracts, which makes patients susceptible to recurrent respiratory infections. Pediatric patients may present with tachypnea, chest pain, and crackles, although it may be difficult to separate acute exam findings from chronic disease.

Epiglottitis

Epiglottitis (supraglottitis), at one time a dreaded inflammation of the supraglottic structures (soft tissue in the area above the vocal cords), usually due to bacterial infection, is now rare in children. With the introduction of a childhood vaccine against *Haemophilus influenzae* type B, the incidence of this life-threatening condition has decreased dramatically. Nevertheless, sporadic cases have been reported among adolescents, adults, and unimmunized children.

Words of Wisdom

Do not do anything to agitate a child with suspected croup or epiglottitis. Doing so could create a laryngospasm and cause closure of the airway.

The classic presentation of epiglottitis is easily distinguishable using the PAT. A child with epiglottitis looks sick and will be anxious, will sit upright in the sniffing position with the chin thrust forward to allow for maximal air entry, and may be drooling because of an inability to swallow secretions. The work of breathing is increased, and pallor or cyanosis may be evident.

Stridor heard on auscultation over the neck, a muffled voice, decreased or absent breath sounds, and hypoxia are all signs of a significant airway obstruction. The SAMPLE history will reveal a sudden onset of high fever and sore throat. Because symptoms progress rapidly, children with epiglottitis are generally sick for only a few hours before they come to medical attention. Remember to ask about immunizations as part of the pertinent medical history for patients suspected of having epiglottitis.

Your goal is to get the child with epiglottitis to an appropriate hospital with a maintainable airway. Because rapidly progressive disease is associated with a risk for acute airway obstruction and respiratory arrest, you should minimize your scene time and not attempt procedures that might agitate the child. Allow the patient to assume a position of comfort, and provide supplemental oxygen only if tolerated by the patient. Do not attempt to look in the mouth because this can precipitate complete airway obstruction, and do not attempt IV access. Be prepared with a bag-mask device in the event of complete obstruction during transport and the need for assisted ventilation. Alert personnel at the

Special Populations

There are some special considerations when suctioning an infant or child's airway. Use a bulb syringe, flexible suction catheter, or rigid (tonsil-tip) suction catheter. Follow these guidelines:

- Avoid vigorous suctioning.
- Avoid upper airway stimulation; vagal stimulation can cause bradycardia and hypoxia.
- Decrease suction negative pressure to 100 mm Hg or less.
- Suction only when withdrawing the catheter.
- Limit suction time to 10 seconds in children and 5 seconds in infants.
- If bradycardia occurs, stop suctioning immediately and oxygenate the child.

receiving facility to the suspected diagnosis and the patient's condition because they will need to mobilize a team for the management of this difficult airway.

Lower Airway Emergencies

Signs and symptoms of a lower airway obstruction include wheezing, a whistling sound caused by air traveling through narrowed air passages within the bronchioles, and/or crackles. Crackles (formerly called rales) are caused by the flow of air through liquid present in the air pouches and smaller airways in the lungs. This airflow produces a crackling sound like that of blowing bubbles through a straw in a glass filled with liquid. The best way to auscultate breath sounds in a pediatric patient is to listen on both sides of the chest at the level of the armpit (**FIGURE 36-20**).

Asthma

Asthma is an acute spasm and inflammation of the bronchioles in the lungs (bronchospasm) and is associated with excessive mucus production. Asthma is typically encountered in children with a pre-existing history of the disease. It is a true emergency if not promptly identified and treated. According to the US Centers for Disease Control and Prevention (CDC), approximately 7.7% of children (5.5 million) currently have asthma.⁸ In between attacks, the child is usually asymptomatic. However, an acute attack can be caused by various triggers, including upper respiratory infections, allergies, changes in environmental temperature, smoke, physical exertion, and emotional stress.

FIGURE 36-20 The best way to auscultate breath sounds in pediatric patients is to listen on both sides of the chest at the level of the armpit.

© Jones & Bartlett Learning.

An acute asthma attack occurs when the hyperreactive bronchioles become narrowed, causing a reduction of airflow through them. The initial response during an acute asthma attack is the result of the immune system's response to the trigger, which releases chemicals called histamines. As the attack progresses, swelling of the mucous membranes in the bronchiolar walls and mucus plugging of the bronchiolar lumen further restrict expiratory airflow. Pulmonary gas exchange is impaired, and the child becomes hypoxicemic.

The signs and symptoms of an acute asthma attack vary, depending on the severity of the attack. You will typically find the child sitting up, in a preferential position, and in obvious respiratory distress. When you are evaluating breathing, you will often note a prolonged expiratory phase, indicating the child's difficulty in expelling air from the lungs. Wheezing is commonly heard during auscultation of the chest, usually during expiration. During a more severe asthma attack, however, wheezing may become so loud that it is audible without a stethoscope. Other signs include tachycardia, tachypnea, and agitation.

Administer oxygen by the method most tolerated by the child: a nonbreathing mask or the blow-by technique.

During your assessment, you should determine whether the child has been prescribed a metered-dose inhaler (MDI) containing a beta-2 agonist (ie, albuterol) or other medication. If so, determine how many puffs, if any, the child took prior to your arrival. Depending on how many, if any, puffs the child has taken from the MDI, you may assist the child with the medication or administer a nebulized updraft of a beta-2 agonist such as albuterol.

Special Populations

The pediatric dose of albuterol depends on the child's weight and may need to be repeated based on the child's clinical response. The dose for albuterol is provided earlier in this chapter.

Medical control or local protocol may determine if the administration of epinephrine 1 mg/mL (1:1,000) subcutaneously in children with severe respiratory distress or failure resulting from a reactive airway disease is an option. Follow local protocols regarding the appropriate pediatric dosage.

as directed by medical control. Ask the child (if old enough) or parent/caregiver if the child has ever been intubated or admitted to the intensive care unit for asthma. If the answer to either of these questions is yes, there is an increased risk that the child will need similar aggressive treatment again.

Other than oxygen, the primary pharmacologic agent used for an acute asthma attack is a beta-2 agonist. Albuterol (Ventolin, Proventil) seems to be the most commonly administered bronchodilator. Other medications, however, such as metaproterenol (Alupent), or isoetharine (Bronkosol), may be administered depending on local protocols. Albuterol (or other beta-2 agonists) is administered through a nebulizer. Always contact medical control prior to administration of any medication as well as following local protocols.

Children experiencing a prolonged asthma attack tend to tire quickly. If the child is showing signs of respiratory failure, begin assisted ventilations with a bag-mask device and 100% oxygen. If needed, bronchodilator therapy can be administered during PPV with a small-volume in-line nebulizer.

Endotracheal intubation may be necessary if prolonged ventilatory support is needed or if bag-mask ventilations are ineffective. Call early for paramedic backup.

Additional treatment consists of monitoring the child's oxygen saturation level and transporting promptly to the hospital. If the child's condition will allow, do not separate the child from the parent or caregiver.

A prolonged asthma attack that is unrelieved may progress into a condition known as status asthmaticus, in which there is minimal air movement. Status asthmaticus is a dire emergency. Although the treatment for status asthmaticus is essentially the same as it is for a mild or moderate asthma attack, it is more aggressive and must be performed en route to the hospital. Many children with status asthmaticus will experience respiratory failure secondary to severe hypoxia, acidosis, and physical exhaustion, and will require assisted ventilations including advanced airway management.

Pneumonia

Pneumonia is a common disease process that infects the lower airway and the lung. Although it can occur at any age, in pediatric patients it is commonly seen in

infants, toddlers, and preschoolers (ages 1 to 5 years). In the United States, 70% of pneumonia-related hospitalizations in children occurred in those younger than 5 years.⁹ Worldwide, according to the World Health Organization, pneumonia accounts for 15% of all deaths in children younger than 5 years.¹⁰ In children, pneumonia is usually caused by a virus. However, as children get older, the incidence of bacterial pneumonia increases. Children with pneumonia typically have a recent history of a cough or cold, or a lower airway infection (ie, bronchitis). Pneumonia can also be caused by direct lung injuries, such as from an accidental ingestion of a chemical or a submersion incident.

Often, pediatric patients with pneumonia will present with unusually rapid breathing or will breathe with grunting or wheezing sounds. Additional signs and symptoms include nasal flaring, tachypnea, crackles, and hypothermia or fever. The patient may also exhibit unilateral diminished breath sounds. Assess the work of breathing by observing for signs of accessory muscle usage. Pneumonia in the infant population may not be tolerated as well as in the older child or adult populations because infants have an increased oxygen demand and less respiratory reserve.

For a pediatric patient with suspected pneumonia, your primary treatment is supportive, consisting of monitoring the patient's airway and breathing status, and administering supplemental oxygen if required. If the child is wheezing, administer a bronchodilator if permitted by your EMS system. Vascular access is generally not indicated for children with pneumonia; however, if the child's condition warrants medication therapy, establish IV or IO access en route to the hospital. A diagnosis of pneumonia must be confirmed in the hospital setting with a chest radiograph, followed by the administration of antibiotics as the primary treatment.

Bronchiolitis

Bronchiolitis is a viral infection that results in inflammation and constriction of the bronchioles and is often caused by RSV.

Bronchiolitis occurs during the first 2 years of life and is more common in males. These infections are most widespread in the winter and early spring. Bronchioles, the tiny airways that lead to alveoli in the lungs, become inflamed, swell, and fill with

mucus. The airways of infants and young children can become easily blocked.

When assessing a pediatric patient, look for signs of dehydration—infants with RSV often refuse liquids. If the RSV has progressed to bronchiolitis, shortness of breath and fever may be present.

Approach the pediatric patient with a calm demeanor and allow for a position of comfort. Treat airway and breathing problems as appropriate. Humidified oxygen is helpful if available. Be prepared to assist ventilations as needed. Call early for paramedic backup if you anticipate the need for advanced airway management.

Pertussis

Pertussis, also known as whooping cough, is a disease caused by a bacterium that is spread through respiratory droplets. As a result of vaccinations, this potentially deadly disease is less common in the United States. The typical signs and symptoms are similar to those of a common cold: coughing, sneezing, and a runny nose. As the disease progresses, the coughing becomes more severe and is characterized by the distinctive whoop sound heard during the inspiratory phase. In infants infected with pertussis, pneumonia or respiratory failure may develop. To treat these pediatric patients, keep the airway patent and transport the patient to the hospital. Because pertussis is contagious, follow standard precautions, including wearing a mask and eye protection.

General Assessment and Management of Respiratory Emergencies

Airway Adjuncts

In children with inadequate ventilation, regardless of the cause, you should use an airway adjunct to maintain a patent airway. Placing the adjuncts correctly starts with choosing the appropriate-size equipment (**TABLE 36-11**). If an airway adjunct is not the correct size for the child's size and age, it may cause more harm than good.

Oropharyngeal Airway

An oropharyngeal (oral) airway should be used for pediatric patients who are unresponsive and in respiratory failure. However, this adjunct should not

TABLE 36-11 Pediatric Equipment: Getting the Size Right

The best way to identify the appropriate-size equipment for a pediatric patient is to use a **length-based resuscitation tape** (Broselow tape). This color-coded tool can estimate weight as well as height in pediatric patients weighing up to 75 lb (34 kg) (**FIGURE 36-21**). The proper sequence for using the tape is the following:

1. Place the pediatric patient supine on a flat surface.
2. Lay the tape next to the pediatric patient with the multicolored side up.
3. Place the red end of the tape at the top of the pediatric patient's head (Red to Head).
4. Place one hand, side down, on top of the pediatric patient's head, covering the red box at the end of the tape.
5. Starting from the pediatric patient's head, run the side of your free hand down the tape.
6. Stretch the tape out the full length of the child, stopping at the heel. If the child is longer than the tape, stop here and use the appropriate adult technique.
7. Place your free hand, side down, at the bottom of the child's heel.
8. Note the color or letter block and weight range on the edge of the tape where your hand is. Say the color or letter out loud.
9. Select the appropriate-size equipment by matching the color or letter on the tape to the color or letter on the equipment.

© Jones & Bartlett Learning.

FIGURE 36-21 Use of a length-based resuscitation tape is the best way to identify the correct size for pediatric equipment, including basic and advanced airway devices and medication doses.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

be used in responsive patients or those who have a gag reflex. In addition, this adjunct should not be used in children who have ingested a caustic (corrosive) or petroleum-based product because it may induce vomiting.

SKILL DRILL 36-2 shows the steps for inserting an oropharyngeal airway in a child.

If a tongue blade is not available, point the airway tip toward the roof of the mouth to depress the tongue. Gently rotate the airway into position as it

passes through the mouth toward the curve of the tongue.

Take care to avoid injuring the hard palate as you insert the airway. Rough insertion can cause bleeding, which may aggravate airway problems and may even cause vomiting. Note also that if the patient's airway is too small, the tongue may be pushed back into the pharynx, obstructing the airway. If the oropharyngeal airway is too large, it may obstruct the larynx.

Skill Drill 36-2 Inserting an Oropharyngeal Airway in a Pediatric Patient

Step 1

Determine the appropriate-size airway by placing the airway next to the face with the flange at the level of the central incisors and the bite block segment parallel to the hard palate. The tip of the airway should reach the angle of the jaw. Or, use a length-based resuscitation tape to determine the appropriate-size airway.

© Jones & Bartlett Learning.

Step 2

Position the patient's airway. In medical patients, use the head tilt–chin lift maneuver, avoiding hyperextension; you may place a towel under the patient's shoulders to assist in holding the position. If the patient has a traumatic injury, use the jaw-thrust maneuver and provide manual in-line stabilization.

Step 3

Open the mouth by applying pressure on the chin with your thumb. Insert the airway by depressing the tongue with a tongue blade applied to the base of the tongue and inserting the airway directly over the tongue blade. Insert the airway until the flange rests against the lips. Reassess the airway after insertion.

Nasopharyngeal Airway

The nasopharyngeal (nasal) airway is typically used for pediatric patients who are responsive. It is well tolerated and not as likely as the oropharyngeal airway to cause vomiting. In pediatric patients, the nasopharyngeal airway is typically used in association with respiratory failure. It is rarely used in infants younger than 1 year.

A nasopharyngeal airway should not be used in patients with nasal obstruction, facial trauma, or moderate to severe head trauma (because this adjunct could increase intracranial pressure and, in cases of basilar skull fracture, the airway could penetrate the skull and injure the brain).

Follow the steps in **SKILL DRILL 36-3** to insert a nasopharyngeal airway in a pediatric patient.

Skill Drill 36-3 Inserting a Nasopharyngeal Airway in a Pediatric Patient

Step 1

Determine the appropriate-size airway by comparing its diameter with the opening of the nostril (naris). Place the airway next to the patient's face to confirm correct length. Position the airway appropriately, using the techniques described for the oropharyngeal airway.

Step 2

Lubricate the airway with a water-soluble lubricant. Insert the tip into the right naris (nostril opening) with the bevel pointing toward the septum, or central divider in the nose.

Step 3

Carefully advance the airway, following the curvature of the anatomy, until the flange rests against the outside of the nostril.

Keep in mind that the external diameter of the airway should not be larger than the diameter of the naris or the child's little finger, and there should be no **blanching** (turning white) of the naris after insertion. As for length, the airway should extend from the tip of the nose to the tragus of the ear. The **tragus** is the small cartilaginous projection in front of the opening of the ear.

The right naris is commonly larger than the left naris. However, if you are inserting the airway on the left side, insert the tip into the left naris upside down, with the bevel pointing toward the **septum**. Move the airway forward slowly approximately 1 inch (2.5 cm) until you feel a slight resistance, and then rotate the airway 180°. Reassess the airway after insertion.

Oxygen Delivery Devices

All ill or injured infants and children should receive supplemental oxygen. The method of oxygen delivery will be determined by the adequacy of the patient's breathing, or tidal volume. In treating infants and children who require supplemental oxygen, the following devices and techniques can be used:

- Blow-by oxygen at 6 L/min provides more than 21% oxygen concentration.
- Nasal cannula at 1 to 6 L/min provides 24% to 44% oxygen concentration.
- Nonrebreathing mask at 10 to 15 L/min provides up to 95% oxygen concentration (unassisted ventilations).
- Bag-mask device (with oxygen reservoir) at 15 L/min provides nearly 100% oxygen concentration (assisted ventilations).

Children need enough air to be delivered for adequate gas exchange in the lungs. Therefore, use of a nonrebreathing mask or the blow-by technique is indicated only for patients who have adequate respiratory rates and tidal volumes. **Tidal volume** is the amount of air that is delivered to the lungs in one inhalation. Because the nonrebreathing mask and blow-by technique deliver oxygen passively, PPV with a bag-mask device is needed in children with inadequate breathing. Children with respirations of less than 12 breaths/min or more than 60 breaths/min, an altered level of consciousness, and/or an inadequate tidal volume should receive assisted ventilations with a bag-mask device.

Blow-by Oxygen

Blow-by oxygen does not deliver a high concentration of oxygen; however, if the child will not tolerate a nonrebreathing mask, the blow-by technique is better than no oxygen at all.

Words of Wisdom

You cannot use a nonrebreathing mask for blow-by oxygen because of the one-way valve. It will not deliver oxygen unless it is applied firmly to the child's face.

After ensuring a patent airway and maintaining proper head position, administration of oxygen via the blow-by technique may require assistance from the parent or caregiver. This method may be less frightening to a child than a mask. In the blow-by technique, an oxygen tube is held near the infant or child's nose and mouth. Allowing a parent or caregiver to hold the device near the child's face may facilitate tolerance. To administer blow-by oxygen:

1. Place oxygen tubing through a small hole in the bottom of an 8-oz (237-mL) cup (**FIGURE 36-22**). A cup is a familiar object that is less likely to frighten young children than an oxygen mask.

FIGURE 36-22 To use the blow-by technique, make a small hole in a 8-oz (237-mL) cup, or use a funnel inserted into the end of the oxygen tubing. Connect tubing to an oxygen source, and hold the cup about 1 to 2 inches (2 to 5 cm) from the child's face. Consider allowing a parent or caregiver to hold the child to reduce the child's anxiety.

© Jones & Bartlett Learning.

FIGURE 36-23 The prongs of the pediatric nasal cannula should not fill the nares entirely.

© Jones & Bartlett Learning.

2. Connect the oxygen tubing to an oxygen source set at 6 L/min.
3. Hold the cup approximately 1 to 2 inches (2 to 5 cm) away from the child's nose and mouth.

Nasal Cannula

Some pediatric patients prefer the nasal cannula, whereas others find it uncomfortable. To apply a nasal cannula:

1. Choose the appropriate-size pediatric nasal cannula. The prongs should not fill the nares entirely (**FIGURE 36-23**). If the nares blanch, select a smaller cannula.
2. Connect the tubing to an oxygen source set at 1 to 6 L/min.

Special Populations

Nasal cannulas are rarely used to administer oxygen in pediatric patients. Infants and children are usually not tolerant of the device, which causes anxiety and increased oxygen demand. Agitating an already hypoxic infant or child may exacerbate the condition.

Nonbreathing Mask

A nonbreathing mask delivers up to 95% oxygen to the patient and allows the patient to exhale all air containing carbon dioxide without rebreathing it (**FIGURE 36-24**). To apply a nonbreathing mask:

FIGURE 36-24 A pediatric nonbreathing mask delivers up to 95% oxygen and allows the patient to exhale air containing carbon dioxide without rebreathing it.

© Jones & Bartlett Learning.

1. Select the appropriate-size pediatric nonbreathing mask. The mask should extend from the bridge of the nose to the cleft of the chin.
2. Connect the tubing to an oxygen source set at 10 to 15 L/min.
3. Adjust the oxygen flow as needed to match the patient's respiratory rate and depth. The reservoir bag should neither deflate completely nor fill to bulging during the respiratory cycle.

Bag-Mask Device

Assisted ventilation with a bag-mask device is indicated for patients who have respirations that are too fast or too slow to provide adequate tidal volume of inhaled oxygen, who are unresponsive, or who do not respond in a purposeful way to painful stimuli.

Assist ventilation of an infant or child using a bag-mask device in the following way:

1. Ensure that you have the appropriate equipment in the right size. The mask should extend from the bridge of the nose to the cleft of the chin, avoiding compression of the eyes (**FIGURE 36-25**). The mask is transparent, so you can observe for cyanosis and vomiting. In addition, mask volume should be small to decrease dead space and avoid rebreathing; however, the bag should contain at least 450 mL of air. Use an infant bag rather than a neonatal bag for infants younger than 1 year; use a pediatric bag for children older than 1 year. Older children and adolescents may need an adult bag. Make sure that there is no pop-off valve

FIGURE 36-25 Proper mask size for bag-mask ventilation is critical. The mask should extend from the bridge of the nose to the cleft of the chin, avoiding compression of the eyes.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

on the bag, or, if there is one, make sure that you can hold it shut as necessary to achieve visible chest rise.

2. Maintain a good seal with the mask on the face. An inadequate mask-to-face seal will result in inadequate tidal volume delivery and a decreased concentration of delivered oxygen.
3. Ventilate at the appropriate rate and volume using a slow, gentle squeeze, not a sharp, quick one. Stop squeezing and begin to release the bag as soon as the chest wall begins to rise, indicating that the lungs are filled to capacity. To keep from ventilating too rapidly, use the phrase “squeeze, release, release.” Say “squeeze” as you squeeze the bag; when you see the chest start to rise, release pressure on the bag and slowly say “Release, release.”

Errors in technique, including providing too much volume with each breath, squeezing the bag too forcefully, or ventilating at too fast a rate, can result in gastric distention or a pneumothorax. Even with the best technique, however, the patient may regurgitate and aspirate the stomach's contents. An inadequate mask-to-face seal or improper head position can lead to inadequately delivered tidal volume and hypoxia.

One-Person Bag-Mask Device Ventilation

Perform one-person bag-mask ventilation in an infant or child according to the steps in **SKILL DRILL 36-4**. Ensure a good mask-to-face seal while maintaining the airway by forming a C with the

thumb and index finger along the mask while the other three fingers form an E along the mandible. With infants and toddlers, support the jaw with only your third fingertip. Be careful not to compress the area under the chin because you may push the tongue into the back of the mouth and block the airway. Keep your fingers on the mandible.

Words of Wisdom

To use the EC clamp technique, form a C with the thumb and index finger along the mask while the other three fingers form an E along the mandible. With infants and toddlers, support the jaw with only your third fingertip. Be careful not to compress the area under the chin because you may push the tongue into the back of the mouth and block the airway. Keep fingers on the mandible.

Two-Person Bag-Mask Device Ventilation

This procedure is similar to one-person ventilation except that it requires two AEMTs, one to maintain an adequate mask-to-face seal and maintain the patient's head position and the other to ventilate the patient. This technique is usually more effective in maintaining a tight seal. Because it is not possible to perform a one-handed jaw-thrust maneuver and also maintain spinal immobilization, ventilating the trauma patient is a two-person skill.

Cardiopulmonary Arrest

Cardiopulmonary arrest in infants and children is most often associated with respiratory failure and respiratory arrest. Children are affected differently than adults when it comes to decreasing oxygen concentrations. An adult becomes hypoxic and the heart gets irritable, and sudden cardiac death occurs from a dysrhythmia. This is often in the form of ventricular fibrillation and is the reason that an automated external defibrillator (AED) is the treatment of choice. A child, however, becomes hypoxic and the heart slows down, becoming more and more bradycardic. The heart will beat slower and become weaker with each beat until no pulse is felt. The overall survival rate from cardiac arrest in the prehospital setting in children is low, with infants having a much worse prognosis than children or adolescents. Approximately 8% of children

Skill Drill 36-4 One-Person Bag-Mask Device Ventilation on a Pediatric Patient

Step 1

Open the airway and insert the appropriate airway adjunct.

Step 2

Hold the mask on the pediatric patient's face with a one-handed head tilt–chin lift maneuver (EC clamp technique). Ensure a good mask-to-face seal while maintaining the airway.

Step 3

Squeeze the bag using the correct ventilation rate of 1 breath every 2 to 3 seconds, or 20 to 30 breaths/min. Allow adequate time for exhalation.

© Jones & Bartlett Learning.

Step 4

Assess the effectiveness of the ventilation by watching for adequate bilateral rise and fall of the chest.

survive.¹¹ Many of those who do survive have permanent brain injury as a result of the arrest. However, the survival rate from only respiratory arrest is 75% to 93%.¹² Therefore, a child who is breathing poorly with a slowing heart rate must be ventilated with high concentrations of oxygen early to try to oxygenate the heart and avoid the development of cardiac arrest. Chapter 15, *BLS Resuscitation*, covers providing CPR to pediatric patients in detail.

The signs, symptoms, and treatment of shock and cardiopulmonary arrest were discussed in

other chapters. The following section will address methods of maintaining and improving circulation in the infant or child, including vascular access (IV and IO) and fluid resuscitation.

Assessment and Management of Circulation Emergencies

Pediatric patients have a larger proportional amount of circulating blood volume than adults, but are more dependent on the actual cardiac

output than adults. A pediatric patient may be in a state of shock while displaying a normal blood pressure. Infants and children have less circulating blood volume than adults do, so the loss of even a small amount of fluid or blood may result in shock.

Shock

Shock is a condition that develops when the circulatory system is unable to deliver sufficient blood to the organs of the body. Shock can result in pediatric cardiac arrest. Although data regarding prehospital pediatric arrest are limited, just as with the adult, early recognition and prompt intervention can prevent permanent disability or death.¹³ Shock is discussed in Chapter 14, *Shock*.

Compared with adults, children can compensate for shock for longer periods of time, maintaining adequate perfusion because of vasoconstriction. However, when hypotension occurs, it does so quickly and unpredictably and may result in rapid deterioration to cardiopulmonary arrest.

Common causes of shock in the pediatric population include hypovolemia (from trauma or illness) and sepsis. Although less common, allergic reactions and poisonings can result in shock. Shock from a primary cardiac event is rare in infants and children.

Greater than 25% blood volume loss significantly increases the risk of shock in children.¹⁴ Signs of shock in children are as follows:

- Tachycardia
- Poor capillary refill (>2 seconds)
- Mental status changes

For comparison, signs of shock in adults are:

- Tachycardia
- Hypotension
- Mental status changes

Blood volume loss greater than 30% to 40% significantly increases risk of shock in adults.¹⁵

Begin treating shock by assessing the ABCDEs, intervening immediately as required; do not wait until you have performed the complete assessment to take action. If cardiac arrest is suspected, the order becomes CABDE (Circulation, Airway, Breathing, Disability, Exposure) because compressions are essential. Pediatric patients in shock often have increased respirations but do not demonstrate a decrease in blood pressure until shock is severe.

In assessing circulation, you should pay particular attention to the following:

- **Pulse.** Assess both the rate and the quality of the pulse. A weak, thready pulse is a sign that a problem exists. The appropriate rate depends on age; a rate of more than 160 beats/min suggests shock.
- **Skin signs.** Assess the temperature and moisture of the hands and feet. How does this compare with the temperature of the skin on the trunk of the body? Is the skin dry and warm, or cold and clammy?
- **Capillary refill time.** Does the fingertip return to its normal color within 2 seconds, or is it delayed?
- **Color.** Assess the patient's skin color. Is it the normal color for this person?
- **Changes.** Changes in pulse rate, skin signs, capillary refill time, and color are all important clues suggesting shock.

Blood pressure is the most difficult vital sign to measure in younger pediatric patients. The cuff must be the proper size: two-thirds the length of the upper arm. The value for normal blood pressure is also age specific. Remember that blood pressure may be normal in a patient with compensated shock. Low blood pressure is a sign of decompensated shock, requiring oxygenation, fluid administration, and immediate transport.

Part of your assessment should also include talking with the parents or caregivers to determine when the signs and symptoms first appeared and whether any of the following has occurred:

- Decrease in urine output (with infants, are there fewer than 6 to 10 wet diapers?)
- Absence of tears, even when the child is crying
- A sunken or depressed fontanelle (infant patient)
- Changes in level of consciousness and behavior

Special Populations

You should carefully assess any infant or child suspected of being in a state of shock. At first, the signs and symptoms may be subtle and hard to detect. A thorough assessment and history and a keen eye will enable you to recognize shock in its earliest stages.

Limit your management to these simple interventions. Time should not be wasted performing field procedures. Ensure that the airway is open and prepare for artificial ventilation, control bleeding, and give supplemental oxygen by mask or blow-by method as tolerated. Continue to monitor airway and breathing. Position the pediatric patient in a position of comfort determined by local protocol. Keep the pediatric patient warm with blankets and by turning up the heat in the patient compartment. Unless it is absolutely critical, time-consuming procedures (ie, IV, IO access) should be performed en route. Establish vascular access and administer NS or 20-mL/kg boluses of lactated Ringer solution as needed to maintain adequate perfusion. After each fluid bolus, reassess the child; several fluid boluses are often needed in children with severe hypovolemia. Provide immediate transport to the nearest appropriate facility and continue monitoring vital signs en route. Contact paramedic backup as needed. Allow a parent or caregiver to accompany the pediatric patient whenever possible.

Words of Wisdom

Shock in children is most likely caused by hypovolemia. Fluid resuscitation with an isotonic crystalloid solution is the mainstay of treatment. Do not waste time with multiple IV insertion attempts when caring for a child in decompensated shock from hypovolemia. Insert an IO needle and begin fluid therapy.

Anaphylactic Shock

Anaphylaxis is a major allergic reaction that involves a generalized, multisystem response to an antigen (foreign substance). The airway and cardiovascular system are important sites of this potentially life-threatening reaction. Common causes are insect stings, medications, or food.

A pediatric patient in anaphylactic shock will have hypoperfusion as well as additional signs such as stridor and/or wheezing, with increased work of breathing. The pediatric patient will also have an altered appearance with restlessness, agitation, and sometimes a sense of impending doom. Hives, an intensely itchy skin rash, are usually present.

Maintain the airway and administer oxygen via a route that is tolerated. If the child is stable, allow

the parent or caregiver to assist in the positioning of the patient, oxygen delivery, and keeping the child calm. Increased agitation and crying, combined with an increased work of breathing, may lead to increased bronchoconstriction. Based on local protocol, assist the parent or caregiver with administering a prescribed epinephrine auto-injector, if available. Transport promptly.

If anaphylactic shock is present, administer epinephrine subcutaneously or via auto injector. Obtain IV or IO access for fluid resuscitation and administer 20 mL/kg of an isotonic crystalloid solution to maintain perfusion. Administer oxygen as needed. Call early for paramedic backup if advanced airway management is anticipated.

Special Populations

Remember, bradycardia in infants and children is almost always the result of severe hypoxia. Provide ventilatory assistance with 100% oxygen. The most common cause of tachycardia in an infant or young child is from fever, dehydration, or pain.

Bleeding Disorders

Hemophilia is a congenital condition in which the patient lacks one or more of the normal clotting factors of blood. There are several forms of hemophilia, most of which are hereditary and some of which are severe. Hemophilia is found predominantly in males. Sometimes bleeding may occur spontaneously. Because the hemophiliac patient's blood does not clot, all injuries, no matter how minor, are potentially serious. Transport a child with hemophilia immediately, and do not delay tourniquet application for life-threatening hemorrhage.

Intravenous Access

Although IV therapy is not performed as frequently in children as it is in adults, the technique, indications, and contraindications in the infant and child are the same as they are for adults. In addition, the same IV solutions and equipment used for adults can be used for pediatric patients, with a few exceptions. See Chapter 13, *Vascular Access and Medication Administration*, for more information on IV therapy.

Words of Wisdom

Helpful tips for vascular access:

- Make sure all equipment is prepared and within easy reach prior to attempting IV access.
- Explain what you are doing and allow the child to see the equipment.
- Wrap the child in a blanket (or consider heat packs) to encourage vasodilation and make veins easier to feel.
- Allow the extremity to hang down and pat or rub the area.
- Take care when using a tourniquet on infants. Often, another provider holding gentle pressure around an extremity is sufficient.
- After two unsuccessful attempts, ask your partner to try.
- In a critical patient, do not waste time trying multiple IV attempts. Instead, insert an IO line.

Catheters

If you are using an over-the-needle catheter (an “angiocath”) to start a pediatric IV, the 20-, 22-, 24-, and 26-gauge catheters are best for insertion (**FIGURE 36-26**). Butterfly catheters are useful for pediatric patients and can be placed in the same locations as over-the-needle catheters and in visible

FIGURE 36-26 Note the difference in sizes of intravenous catheters.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

scalp veins in infants. However, butterfly catheters are associated with a higher rate of infiltration because a stainless steel needle lies in the vein, instead of the Teflon catheter or an over-the-needle catheter.

Administration Sets

Fluid control for pediatric patients is important. Using a special type of microdrip set called a **Volutrol** (also called Buretrol) allows you to fill the large drip chamber with a specific amount of fluid and administer only this amount to avoid fluid overload. The 100-mL calibrated drip chamber on the Volutrol can be shut off from the IV bag.

If your EMS system does not use the Volutrol, a regular microdrip administration set can be used; however, use caution when administering fluid through these administration sets.

IV Locations

When starting IV access, take both the child and the parent or caregiver into consideration. The parent can become as stressed as the child. If the condition of the child permits, take time to thoroughly explain the procedure to both the child and the parent or caregiver. When possible, allow the infant or child to sit on the parent's or caregiver's lap when starting IV access.

The younger the child, the fewer choices you have for IV sites. Hand veins are painful and difficult to manage in younger children; however, they remain the location of choice for starting peripheral IV lines.

Protecting the IV site after it has been established is critical and is sometimes best accomplished by immobilizing the site with an arm board before cannulation. One of the better techniques for starting pediatric IV lines is to use a penlight to illuminate the veins on the back of the hand. Shine the light through the palm side of the hand to illuminate the veins on the dorsal aspect of the hand. After a suitable site is located, mark the vein with a pen so you can find the location after you turn off the penlight. Proceed with obtaining IV access, using the mark you created as a guide. Sometimes the best choice is an antecubital vein, especially if the child is critically ill or injured and needs fluid resuscitation or medication therapy. **FIGURE 36-27** illustrates the different sites for starting IV lines in infants and children.

FIGURE 36-27 Sites for intravenous lines in infants and children are the hands, antecubital fossa, the saphenous veins at the ankle, and the feet.

Used with permission of the American Academy of Pediatrics, Pediatric Education for Prehospital Professionals, © American Academy of Pediatrics, 2000.

Special Populations

Most pediatric patients do not require prehospital IV therapy. Do not start an IV line in an infant or child unless it is absolutely necessary (for example, severe shock or hypoglycemia). Remember that unnecessarily agitating a child can exacerbate the child's condition, especially if the child is already hypoxic.

Intraosseous Access

Intraosseous (IO) infusion is used for emergency vascular access in pediatric patients as defined by protocol when immediate IV access is difficult or impossible. When placed correctly, the IO needle will rest in the **medullary canal**, the space within the bone that contains bone marrow. IO access should be attempted immediately if you are unable to obtain IV access.¹⁶ A general guideline is to attempt IO access if IV access is not successful within three attempts or 90 seconds in a critically ill or injured pediatric patient, as allowed by local protocols. Often these children are experiencing a life-threatening situation such as cardiac arrest, status epilepticus, or progressive shock. An IO infusion is contraindicated if a secure IV line is available or if a possible fracture exists in the same bone in which you plan to insert the IO needle.

The IO needle is usually inserted in the proximal tibia with a special IO needle (**FIGURE 36-28**).

FIGURE 36-28 Standard pediatric intraosseous needles.

Courtesy of VidaCare Corporation (www.vidacare.com).

Products that may be used include the FAST1, the EZ-IO, and the Bone Injection Gun (BIG). A commonly used IO catheter is the **Jamshidi needle**. This double needle, consisting of a solid-bore needle inside a sharpened hollow needle, is pushed into the bone with a screwing, twisting action. After the needle pops through the bone, the solid needle is removed, leaving the hollow steel needle in place. Standard IV tubing is then attached to this catheter.

Anything that can be administered intravenously can be administered through an IO line (such as isotonic fluids and medications). The IO lines require full and careful stabilization because they rest at a 90° angle to the bone and are easily dislodged. Stabilization is critical for these lines to

maintain adequate flow. Stabilize the IO needle in the same manner that you would any impaled object. Follow the steps in **SKILL DRILL 36-5** to establish an IO infusion in the pediatric patient. Before you begin, remember to look for any discoloration or particles floating in the IV fluid. If found, discard and choose another bag of fluid. Also, keep in mind that it is possible to fracture the bone during insertion of the IO. If this happens, you should remove the IO needle and switch to the other leg.

As with any invasive procedure, there are potential complications with IO infusion that you must be aware of. With proper technique, the following potential complications may be avoided:

- Compartment syndrome
- Failed infusion
- Growth plate injury
- Bone and muscle inflammation caused by infection (**osteomyelitis**)

- Skin infection
- Bony fracture

Fluid Resuscitation

As previously mentioned, appropriate fluid administration in the pediatric patient is crucial; IV fluids must be administered based on the child's clinical condition. If too much fluid is administered, overload can result and cause acute left-side heart failure and pulmonary edema. Conversely, administering insufficient fluid volumes will not be effective in treating the child's condition.

Fluid resuscitation for the infant or child in hypovolemic shock begins with an initial bolus of 20 mL/kg of an isotonic crystalloid solution (for example, NS, lactated Ringer solution), followed by a careful reassessment. Administer further boluses of 20 mL/kg as needed to maintain adequate perfusion.

YOU are the Provider

Part 4

After diluting dextrose 50% (D₅₀) into dextrose 10% (D₁₀), you estimate the patient's weight at 18 kg (39 lb). Your protocols state that for hypoglycemia in a child older than 1 year, the beginning dosage of D₁₀ is 0.5 to 1 g/kg via slow IV push. You elect to start at the 0.5-g/kg dose, and prepare 90 mL of D₁₀. You briefly run the IV line wide open for 2 to 3 seconds to ensure patency, and then slowly administer the desired dose of dextrose. After approximately 60 seconds, you recheck the patient's blood glucose level and find that it has increased to 134 mg/dL. You also note that the patient is beginning to take gasping breaths on her own, as well as have some movement in her extremities. After confirming that the patient is now beginning to breathe adequately, you direct your partner to stop ventilations, and place the patient on a nonbreathing mask at 15 L/min. You contact the receiving hospital and inform them of the patient's condition and your 8-minute estimated time of arrival. Approximately 4 minutes later, the patient is responsive, alert and oriented, and crying for her mother. In an effort to calm the patient, you ask your partner to pull over to the side of the road, so that you can have the mother come to the back of the ambulance. After the patient's mother is in the back of the ambulance, you ensure that she is properly secured on the bench seat, and she consoles her daughter. You then ask the driver to resume transport to the hospital, now in nonemergency mode. On your arrival at the ED, you turn over care to the awaiting nurse.

Recording Time: 24 Minutes

Respirations	30 breaths/min
Pulse	130 beats/min
Skin	Warm and dry
Blood pressure	90 mm Hg—palpated
Oxygen saturation (SpO₂)	99% on 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

8. What are the indications and contraindications for dextrose administration in pediatric patients?
9. If this patient should require IV fluid, how much fluid should she receive?

Skill Drill 36-5 Pediatric IO Access and Infusion**Step 1**

Ensure you have selected the proper IV fluid. Check for clarity and expiration date. Select the appropriate equipment, including an IO needle, syringe, saline, and extension set. A three-way stopcock may also be used to facilitate easier fluid administration.

**Step 2**

Select the proper administration set. Connect the administration set to the bag. Prepare the administration set. Fill the drip chamber and flush the tubing. Make sure all air bubbles are removed from the tubing. Prepare the syringe and extension tubing.

**Step 3**

Cut or tear the tape. Follow standard precautions (this must be done before IO puncture). Identify the proper anatomic site for IO puncture. To miss the epiphyseal (growth) plate, you should measure two fingerbreadths below the knee on the medial side of the leg.

**Step 4**

Cleanse the site appropriately. Perform the IO puncture as follows: Stabilize the tibia. Place a folded towel underneath the knee and hold in such a manner as to keep your fingers away from the site of puncture. Insert the needle at a 90° angle to the leg. Advance the needle with a twisting motion until a “pop” is felt.

(continues)

Skill Drill 36-5 Pediatric IO Access and Infusion (*continued*)**Step 5**

Unscrew the cap, and remove the stylet from the needle.

**Step 6**

Attach the syringe and extension set to the IO needle. Pull back on the syringe to aspirate blood and particles of bone marrow to ensure placement. Slowly inject saline to ensure proper placement of the needle. Watch for infiltration, and stop the infusion immediately if noted. Connect the administration set, and adjust the flow rate as appropriate. Fluid does not flow well through an IO needle, and boluses are given by administering the fluid using the syringe.

**Step 7**

Secure the needle with tape, and support it with a bulky dressing. Stabilize in place in the same manner that an impaled object is stabilized. Dispose of the needle in the proper container.

Words of Wisdom

Remember to ask the parent or caregiver how much the child weighs and then convert the weight in pounds to kilograms. If the weight of the child is unknown, use the following formula to estimate the weight in kilograms:

$$(\text{Age [in years]} \times 2) + 8 = \text{Weight in kilograms}$$

When administering IV fluids, it is crucial to obtain as accurate an estimate of the child's weight as possible.

In children who require multiple IV fluid boluses, you should carefully and frequently assess their breath sounds, noting signs of pulmonary edema (for example, crackles, rhonchi).

Assessment and Management of Neurologic Emergencies

There are several causes of altered mental status in children. Some of the most common causes are hypoglycemia, hypoxia, seizure, and drug or alcohol ingestion. The parent or caregiver is an important

Words of Wisdom

Because most cases of cardiopulmonary arrest in infants and children are related to respiratory failure, oxygen is the most common medication that you will administer to them in the prehospital setting. Most pediatric emergencies can be managed by maintaining a patent airway, administering 100% oxygen, and transporting to the hospital.

resource for you when you are gathering information regarding the baseline neurologic status of the pediatric patient. A child with altered mental status may appear sleepy, lethargic, combative, or even unresponsive to tactile stimulus. Be diligent about assessing and managing the airway because pediatric patients may be susceptible to airway obstructions from their large tongues.

Altered Mental Status

People who are aware of themselves and their surroundings are said to be responsive. Nonverbal infants may demonstrate responsiveness by following a person's face or an object (tracking), by babbling and cooing, or by crying. Infants and children may exhibit an altered mental status in many ways, including lack of response to vocal commands and pain, combative behavior, confusion, thrashing about, drifting into and out of an alert state, or a change in the pitch and nature of their cry.

The mnemonic AEIOU-TIPS reflects the major causes of altered mental status. See Chapter 19, *Neurologic Emergencies*, for a discussion of AEIOU-TIPS and other causes of altered mental status.

The signs and symptoms of altered mental status vary widely from simple confusion to coma. Management of altered mental status focuses on the ABCs and transport. If the pediatric patient's level of consciousness is low, the child may not be able to protect the airway. Ensure a patent airway and adequate breathing through a nonrebreathing mask or a bag-mask device. Pediatric patients with

an altered level of consciousness may have inadequate breathing despite spontaneous respiratory effort, based on an inadequate respiratory rate or inadequate tidal volume. Transport to the hospital.

Seizures

A seizure is the result of disorganized electrical activity in the brain. It can be frightening to witness a seizure in a pediatric patient. Therefore, it is important to reassure the family and to approach assessment and management in a calm, step-by-step manner. Common causes of seizures in children include the following:

- Child abuse
- Electrolyte imbalance
- Fever
- Hypoglycemia (low blood glucose level)
- Infection
- Ingestion
- Hypoxia
- Medications
- Poisoning
- Seizure disorder
- Recreational drug use
- Head trauma
- Idiopathic (no cause can be found)

Seizures in children may appear in several different ways, depending on the age of the child. Seizures in infants can be extremely subtle, consisting only of an abnormal gaze, sucking motions, or “bicycling” motions. In older children, seizures are more obvious and typically consist of repetitive muscle contractions and unresponsiveness.

After a seizure has stopped, the patient's muscles relax, becoming almost flaccid, or floppy, and the breathing becomes labored (fast and deep). This is the postictal state. The longer and more intense the seizure is, the longer it will take for this imbalance to correct itself. Likewise, longer and more severe seizures will result in longer postictal unresponsiveness and confusion. When the pediatric patient regains a normal level of responsiveness, the postictal state is over.

Seizures that continue every few minutes without regaining responsiveness or last longer than 30 minutes are referred to as status epilepticus. Recurring or prolonged seizures should be considered potentially life-threatening situations in which pediatric patients need emergency medical care. If

Words of Wisdom

Always check the glucose level in any patient with an altered mental status.

FIGURE 36-29 In a child having a seizure, position the head to open the airway and clear the airway with suction. Consider placing the patient in the recovery position if the patient is actively vomiting and suction is inadequate to control the airway.

© Jones & Bartlett Learning.

the pediatric patient remains unresponsive or continues to seize, protect the pediatric patient from self-harm and call for paramedic backup. These pediatric patients need advanced airway management and medication to stop the seizure.

Securing and protecting the airway are your priorities. Position the head to open the airway. Clear the mouth with suction. Consider placing the pediatric patient in the recovery position if the child is actively vomiting and suction is inadequate to control the airway (**FIGURE 36-29**). Provide 100% oxygen by nonrebreathing mask or blow-by method. If there are no signs of improvement, begin bag-mask device ventilation with appropriate-size equipment with supplemental oxygen. Transport the pediatric patient to the appropriate facility.

Febrile Seizures

Febrile seizures are caused by an abrupt rise in body temperature and occur in approximately 2% to 4% of children younger than 5 years.¹⁷ Most pediatric seizures are caused by fever alone, which is why they are called febrile seizures.

These seizures typically occur on the first day of a febrile illness, are characterized by **generalized tonic-clonic seizures**, and last less than 15 minutes with a short postictal phase or none at all. The seizures may be a sign of a more serious problem, such as meningitis. Obtain a history from the caregivers because these children may have had a febrile seizure in the past.

If you are called to care for a child who has had a febrile seizure, you often will find that the patient

FIGURE 36-30 Following a febrile seizure, carefully assess the child's airway, breathing, circulation, disability, and exposure (ABCDEs). Then begin cooling measures and prepare the child for transport.

© American Academy of Orthopaedic Surgeons.

Words of Wisdom

A febrile seizure is caused by an abrupt rise in body temperature. It is not necessarily how high the fever gets, but how quickly it gets there.

is awake, alert, and fully interactive when you arrive. Keep in mind that a persistent fever can result in another seizure. Carefully assess the ABCDEs, begin cooling measures with tepid (not cold) water, and provide prompt transport; all children with febrile seizures need to be seen in the hospital setting (**FIGURE 36-30**).

Establish IV or IO access and obtain a blood glucose reading; administer glucose if the child is hypoglycemic.

Meningitis

Meningitis is an inflammation of the tissues, called the meninges, that cover the spinal cord and brain. It is caused by an infection by bacteria, viruses, fungi, or parasites. If left untreated, meningitis can result in permanent brain damage or death. The ability to recognize a patient who may have meningitis is an important skill for AEMTs to have.

Meningitis can occur in both children and adults, but some people are at greater risk than others, as follows:¹⁸

- Males
- Newborn infants
- Geriatric patients

- Those with a prior history of meningitis
- Those living in crowded conditions such as in camps, day care centers, schools, and college dormitories
- Children who have not received proper immunizations
- Those with compromised immune systems (such as HIV/AIDS [human immunodeficiency virus/acquired immunodeficiency syndrome] or cancer) or a nonfunctioning spleen
- Those who have sustained head trauma or undergone brain surgery
- Those with shunts, pins, or other foreign bodies within their brain or spinal cord

At especially high risk are children with a ventriculoperitoneal shunt. Ventriculoperitoneal shunts drain excess fluids from around the brain into the abdomen. These children with special needs have tubing that can usually be seen and felt just under the scalp.

The signs and symptoms of meningitis vary, depending on the age of the patient.¹⁹ Fever, headache, and altered level of consciousness are common symptoms of meningitis in patients of all ages. Changes in level of consciousness can range from a mild or severe headache to confusion, lethargy, and/or an inability to understand commands or interact appropriately. The child may also experience a seizure, which may be a first sign of meningitis. Infants younger than 2 to 3 months can have apnea, cyanosis, fever, a distinct high-pitched cry, or hypothermia.

In describing children with meningitis, physicians often use the term *meningeal irritation* or *meningeal signs* to describe pain that accompanies movement. Bending the neck forward or back increases the tension within the spinal canal and stretches the meninges, causing a great deal of pain (**nuchal rigidity**). This results in the characteristic stiff neck of children with meningitis, who will often refuse to move their neck, lift their legs, or curl into a “C” position, even if coached to do so. One sign of meningitis in an infant is increasing irritability, especially when being handled. Another sign is a bulging fontanelle without crying.

One form of meningitis deserves special attention. *Neisseria meningitidis* is a bacterium that causes a rapid onset of meningitis symptoms, often leading to shock and death. Children with *N meningitidis* typically have small, pinpoint, cherry-red

FIGURE 36-31 Children with *Neisseria meningitidis* typically have small, pinpoint, cherry-red spots or a larger purple or black rash.

© Mediscan/Alamy Stock Photo.

spots or a larger purple or black rash (**FIGURE 36-31**). This rash may be on part of the face or body. These children are at serious risk of sepsis, shock, and death.

All patients with possible meningitis should be considered highly contagious. Therefore, follow standard precautions whenever you suspect meningitis and follow up with the hospital to learn the patient's final diagnosis. If you have been exposed to saliva and respiratory secretions from a child with *N meningitidis*, you should receive antibiotics to protect yourself and others from the bacteria. This is particularly true if you managed the patient's airway. If you were not in close contact with the pediatric patient or the patient's respiratory secretions, you do not need treatment.

Safety

Some forms of meningitis are highly contagious. Use standard precautions whenever you suspect meningitis, including mask and eye protection when there is coughing, sneezing, or any other possibility of contact with the patient's respiratory secretions. Local protocols may also call for putting a mask on the patient.

Provide these pediatric patients with supplemental oxygen and assist with ventilations if necessary. Reassess the child's vital signs frequently as you transport the patient to the highest level of

service available. If the patient's vital signs are unstable, obtain vascular access and administer IV fluids as needed to maintain adequate perfusion.

Assessment and Management of Gastrointestinal Emergencies

As with any injury or complaint in the abdominal region, the signs and symptoms of a gastrointestinal emergency may be vague in nature. The abdominal wall muscles are not as developed, which leaves this region more susceptible to injury. Pediatric patients may not be able to pinpoint the exact site where the pain or discomfort originates, but will complain of diffuse tenderness. Never take a complaint of abdominal pain and discomfort lightly because a large amount of bleeding may occur within the abdominal cavity without any outward signs of shock. Remember that liver and splenic injuries are common in this age group and may result in life-threatening emergencies. The pediatric patient needs to be monitored for signs and symptoms of shock, which include an altered mental status; pale, cool skin; tachypnea; tachycardia; and bradycardia (late sign).

A common source of gastrointestinal upset is the ingestion of certain foods, such as milk or ice cream (lactose intolerance), or unknown substances. In most cases, you will be faced with a pediatric patient who is experiencing abdominal discomfort with nausea, vomiting, and/or diarrhea. This can become a concern because both vomiting and diarrhea can cause dehydration in children.

Appendicitis is also common in pediatric patients, and if untreated can result in peritonitis (inflammation of the peritoneum, which lines the abdominal cavity) or shock. Pediatric patients with appendicitis will typically present with a fever and pain on palpation of the right lower abdominal quadrant. Rebound tenderness is a common sign associated with appendicitis. Remember that constipation also can be a cause of abdominal pain in children. If you suspect appendicitis, immediately transport the pediatric patient to the hospital for further evaluation.

Because the pediatric population is sensitive to fluid loss, obtain a thorough history from the parent

or primary caregiver. In particular, ask questions such as:

- How many wet diapers has the child had today?
- Is your child tolerating liquids, and is the child able to keep them down?
- How many times has your child had diarrhea and for how long?
- Are tears present when your child cries?

These questions can help to determine just how dehydrated the pediatric patient may be. If the pediatric patient is dehydrated, transport to the hospital for further care.

Assessment and Management of Toxicologic Emergencies

Poisoning is common among children. It can occur by ingesting, inhaling, injecting, or absorbing a toxic substance. Common sources of poisoning in children include the following:

- Alcohol
- Aspirin, acetaminophen
- Household cleaning products (such as bleach and furniture polish)
- Houseplants
- Iron
- Prescription medications
- Illicit (street) drugs (such as crack, cocaine, or phencyclidine [PCP])
- Vitamins

The signs and symptoms of poisoning vary widely, depending on the substance and the age and weight of the child. The pediatric patient may appear normal at first, even in serious cases, or may be confused, sleepy, or unresponsive.

Infants may be poisoned as a result of being fed a harmful substance by a sibling, parent, or caregiver, or as a result of child abuse. Infants can be exposed to drugs and poisons left on floors and carpeting. They can also be exposed in a room or automobile in which harmful and illicit drugs such as cigarettes, crack, cocaine, or PCP are being smoked. Toddlers are curious and often ingest poisons when they find them in the home or garage (**FIGURE 36-32**). For example, some people store petroleum products in soda bottles. Toddlers may believe the substance to be soda. Adolescents are more likely to have

FIGURE 36-32 A curious child will try to taste or swallow almost any substance. A common victim of accidental ingestion of dangerous compounds is the unwatched toddler.

© Jones & Bartlett Learning.

ingested alcohol and street drugs while at parties or during a suicide attempt.

After you have completed your primary survey and addressed any immediate life threats, you should ask the caregiver the following questions:

- What is the substance or substances involved?
- Approximately how much of the substance was ingested or involved in the exposure (eg, number of pills, amount of liquid)?
- What time did the incident occur?
- Has the child vomited?
- How much does the child weigh?
- Are there any changes in behavior or level of consciousness?
- Was there any choking or coughing after the exposure? (These can be signs of airway involvement.)

Contact the national Poison Control hotline for assistance in identifying poisons (1-800-222-1222). To treat a pediatric patient exposed to a poisonous substance, first perform an external decontamination. Remove tablets or fragments from the patient's mouth, and wash or brush poison from the skin. Treatment focuses on support: maintaining the

pediatric patient's ABCs and monitoring breathing. Provide oxygen and perform ventilations if necessary. If the patient demonstrates signs and symptoms of shock, position the child supine, keep the child warm, and transport promptly to the nearest appropriate hospital.

In some cases, you will give activated charcoal to pediatric patients who have ingested poison, if approved by medical control or local protocol. Activated charcoal is not indicated for pediatric patients who have ingested an acid, an alkali, or a petroleum product; who have a decreased level of consciousness and cannot protect their airway; or who are unable to swallow. If local protocol permits, you will likely carry plastic bottles of premixed suspension, each containing up to 50 g of activated charcoal. Some common trade names for the suspension form are Insta-Char, Actidose, and LiquiChar. The usual dose for a child is 0.5 to 1 g of activated charcoal per kilogram of body weight, which generally equates to 10 to 25 g for small children and 25 to 50 g for larger children.²⁰ Chapter 23, *Toxicology*, discusses the administration of activated charcoal in detail.

Words of Wisdom

Have the American Association of Poison Control Centers number (1-800-222-1222) handy for suspected poisonings.²¹ This free service is available 24 hours per day, 7 days per week.

Assessment and Management of Dehydration Emergencies

Dehydration occurs when fluid losses are greater than fluid intake. The most common cause of dehydration in children is vomiting and diarrhea. If left untreated, dehydration can lead to shock and eventually death. Infants and children are at greater risk than adults for dehydration because their fluid reserves are smaller than those in adults. Life-threatening dehydration can overcome an infant in a matter of hours.

Dehydration can be mild, moderate, or severe. The severity of the dehydration can be gauged by looking at several clues (**TABLE 36-12**). For example, an infant with mild dehydration may have dry lips and gums, decreased saliva, and fewer wet diapers

TABLE 36-12 Vital Signs and Symptoms of Dehydration

	Mild Dehydration	Moderate Dehydration	Severe Dehydration
Pulse	Normal	Increased	Increased; >160 beats/min is sign of impending shock in pediatric patients, except newborns
Level of activity	Normal or slowed	Slowed	Variable, weak to unresponsive
Urine output	Decreased	Decreased	No output
Skin	Normal	Cool, mottled; poor turgor	Cool, clammy; poor turgor; delayed capillary refill time
Mouth	Decreased saliva	Dry mucous membranes	Dry mucous membranes
Eyes	Normal	No tears	Sunken eyes
Anterior fontanelle	Normal to sunken	Sunken	Extremely sunken
Level of consciousness	Normal	Altered	Altered; lethargic
Blood pressure	Normal	Normal	Normal to low

© Jones & Bartlett Learning.

**FIGURE 36-33** An infant with dehydration may exhibit tenting or poor skin turgor.

Courtesy of Ronald Dieckmann, M.D.

throughout the day. As the dehydration grows more severe, the lips and gums may become dry, the eyes may look sunken, and the infant may be sleepy and/or irritable, refusing bottles. The skin may be loose and have no elasticity; this is called poor skin turgor (**FIGURE 36-33**). Also, infants may have sunken fontanelles.

Young children can compensate for fluid losses by decreasing blood flow to the extremities and directing blood flow to vital organs such as the brain and heart. Children who are moderately to severely dehydrated may have mottled, cool, clammy skin

and delayed capillary response time. Respirations will usually be increased. Be aware that blood pressure may remain within a normal range while the pediatric patient is in shock, because the compensatory mechanisms are still in place.

Emergency medical care should include careful attention while assessing the ABCDEs and obtaining baseline vital signs. All pediatric patients with signs and symptoms of moderate to severe dehydration should be transported to the ED for further evaluation and treatment.

Assessment and Management of Fever Emergencies

Fever is a common reason parents or caregivers call 9-1-1. Simply defined, fever is an increase in body temperature, usually in response to an infection. Body temperatures of 100.4°F (38°C) or higher are considered to be abnormal. Fevers have many causes and are rarely life-threatening events. However, do not underestimate the potential seriousness of fevers, such as those that occur in conjunction with a rash, which is a sign of a serious illness such as meningitis. Common causes of a fever in pediatric patients include the following:

- Infection, such as pneumonia, meningitis, or urinary tract infection

- Status epilepticus
- Neoplasm (cancer)
- Drug ingestion (aspirin)
- Collagen vascular disease, including arthritis and systemic lupus erythematosus (rash across the nose)
- High environmental temperature

Note that there are other conditions in which the body temperature increases that are not a fever. Hyperthermia differs from fever in that it is an increase in body temperature caused by an inability of the body to cool itself. Hyperthermia is typically seen in warm environments, such as a closed car on a hot day.

An accurate body temperature is an important vital sign for pediatric patients (**TABLE 36-13**). A rectal temperature is the most accurate for infants to toddlers. Older children will be able to follow directions if placing a thermometer under the tongue or under the arm.

A fever can have several causes, such as a viral or a bacterial infection. Depending on the source of infection, the pediatric patient may present with additional signs of respiratory distress, shock, a stiff neck, a rash, skin that is hot to the touch, flushed cheeks, seizures, sensitivity to light, and bulging fontanelles in an infant. Assess the patient for other signs and symptoms such as nausea, vomiting, diarrhea, decreased feedings, and headache.

TABLE 36-13 Pediatric Normal Temperatures

Age	Temperature (°F)
Neonate (0 to 1 month)	98° to 100° (37°C to 38°C)
Infant (1 month to 1 year)	96.8° to 99.6° (36°C to 37.5°C)
Toddler (1 to 2 years)	96.8° to 99.6° (36°C to 37.5°C)
Preschool age (3 to 5 years)	98.6° (37°C)
School age (6 to 12 years)	98.6° (37°C)
Adolescent (12 to 15 years)	98.6° (37°C)

Data from American Heart Association (AHA). Vital signs in children. In: AHA. Pediatric Advanced Life Support. Dallas, TX: AHA; 2015.

A pediatric patient with a fever may require only minimal interventions in the field. Provide immediate transport and manage the patient's ABCs. Follow standard precautions if you suspect that the patient may have a communicable disease such as meningitis.

Unless associated with shock or severe dehydration, IV therapy is generally not necessary in a child with fever.

Special Populations

Do not induce shivering in a child with fever, which may in turn increase body temperature.

Assessment and Management of Hypoglycemia Emergencies

Hypoglycemia is defined as an abnormally low blood glucose level. Infants and children have limited stores of glucose, which can be quickly depleted in times of illness, injury, or stress. You must recognize that hypoglycemia is a life-threatening emergency that requires immediate treatment. If hypoglycemia is unrecognized or treatment is delayed, permanent brain damage or death can result.

Words of Wisdom

Although hypoglycemia is more common in children with diabetes, physical exertion, illness, or injury can result in hypoglycemia in children without diabetes. Remember to assess blood glucose levels in all ill or injured children with an altered mental status or bizarre behavior.

General signs and symptoms of hypoglycemia include hunger, malaise, tachycardia, tachypnea, diaphoresis, and tremors. The severity of the patient's clinical presentation depends on how low the blood glucose level has dropped. You should obtain a blood glucose reading in any infant or child that you suspect is hypoglycemic. Normal blood glucose levels range from 80 to 120 mg/dL.

In children with a known history of diabetes, ask the parent or caregiver the following questions.

Allow children to answer the questions if they are old enough and understand what you are asking:

1. Have you taken your insulin today? If so, what was the dosage?
2. Has your medication recently changed?
3. When was the last time that you ate? What did you eat?
4. Have you been playing outside or otherwise exerting yourself?

Management of hypoglycemia begins by administering 100% oxygen or assisted ventilation if needed. Monitor vital signs closely. Treat the symptomatic child with glucose if the blood glucose reading is less than 80 mg/dL.

If the child is responsive and alert enough to swallow, administer oral glucose as allowed by local protocol. If, however, the child has an altered mental status or is otherwise incapable of swallowing, administer IV glucose in the following doses:

- For age 1 year and older, administer 0.5 to 1 g/kg of 25% dextrose (D_{25}) via slow IV/IO push. This dose may be repeated as necessary.
- For infants and neonates, administer 200 to 500 mg/kg slow IV/IO push. This dose may be repeated as necessary. Do not exceed a maximum concentration of 12.5% (vasculature extremely sensitive to high concentrations).
- D_{10} may be given in place of D_{25} . Administer 0.5 to 1 g/kg slow IV/IO push. This dose may be repeated as necessary.

If an IV line cannot be established, insert an IO needle. If vascular access (IV or IO) is not available, medical control may order the administration of 1 mg of glucagon via IM injection.

Repeat a blood glucose reading 10 to 15 minutes following the administration of glucose. If the patient is still symptomatic and the blood glucose reading remains below 80 mg/dL, repeat the glucose as needed.

Assessment and Management of Hyperglycemia Emergencies

Hyperglycemia is an abnormally high blood glucose level. It can either be the presenting problem in a child with new-onset diabetes mellitus or it may occur as a complication in a child with a known history of diabetes. If not recognized or promptly

Words of Wisdom

Use the following guide to dilute D_{50} (0.5 g/mL) for pediatric use:

- D_{50} to D_{25}
 - D_{50} is supplied in an ampule with 25 g of dextrose in 50 mL of water. Push out 25 mL of the D_{50} and draw 25 mL of NS into the ampule, agitating to mix. (Mix 1 part D_{50} with 1 part NS, for a total of 12.5 g in 50 mL.)
- D_{50} to D_{10}
 - Draw 4 mL of D_{50} into a 20-mL syringe. Draw 16 mL of NS into the same syringe, agitating to mix. (Mix 1 part D_{50} with 4 parts NS, for a total of 2 g in 20 mL.)
- D_{25} to D_{10}
 - Use the prepared D_{25} in 50 mL as discussed above. Push out 40 mL of the D_{25} and draw 40 mL of NS into the ampule, agitating to mix, for a total of 5 g in 50 mL.

treated, hyperglycemia can result in severe dehydration and DKA, both of which are potentially life threatening.

During your assessment of the child with suspected hyperglycemia, you will typically find that a dose of insulin was missed, a greater proportion of food was eaten compared with the dose of insulin, or the insulin pump malfunctioned.

Like hypoglycemia, the signs and symptoms of hyperglycemia depend on how high the blood glucose level is. During your assessment, ask the same questions of the child or parent as you did for suspected hypoglycemia.

Management of hyperglycemia begins by administering 100% oxygen or assisted ventilation if needed. Monitor vital signs closely. Obtain IV access and administer 20-mL/kg boluses of NS or lactated Ringer solution as needed to maintain adequate perfusion. Children with hyperglycemia and DKA are often severely dehydrated.

Closely monitor the patient's ABCs and be prepared to adjust your treatment accordingly. The patient with DKA desperately needs insulin; however, this is not a drug that is administered in the pre-hospital setting. Therefore, immediate transport to the closest appropriate facility is critical.

If you are unable to obtain IV access, insert an IO needle. If the patient's respiratory status deteriorates, call for paramedic backup.

Words of Wisdom

If you are unable to determine whether a child with an altered mental status has hypoglycemia or hyperglycemia (ie, glucometer failure), administer glucose. If the child is experiencing DKA, the extra glucose likely will not cause further harm. However, if the child is hypoglycemic, the glucose could be lifesaving.

Assessment and Management of Drowning Emergencies

Drowning is the number one cause of unintentional death among children ages 1 to 4 in the United States.²² At this age, children often fall into swimming pools and lakes, but many drown in bathtubs and even buckets of water. Older adolescents, who account for the most drownings after toddlers, drown when swimming or boating; alcohol is frequently a factor. Chapter 34, *Environmental Emergencies*, discusses drowning in greater detail.

The principal cause of injury in a drowning incident is lack of oxygen. Even a few minutes (or less) without oxygen affects the heart, lungs, and brain, causing life-threatening problems such as cardiac arrest, respiratory failure, and coma. Submersion in icy water can rob the body of heat, causing hypothermia. Although a few patients subjected to submersion hypothermia have survived long periods in cardiac arrest in icy water, most people in this situation die. Diving into the water, of course, increases the risk of neck and spinal cord injuries.

Signs and symptoms of a drowning patient will vary based on the type and length of submersion. These pediatric patients may present with coughing; choking; airway obstruction; difficulty breathing; altered mental status; seizure activity; unresponsiveness; fast, slow, or no pulse noted; pale, cyanotic skin; and abdominal distention from ingestion of fluids.

Safety is critical when dealing with a submersion emergency. In submersion situations, always take steps to ensure your own safety when rescuing the patient from the water. Do not become a victim yourself! After the pediatric patient is successfully removed from the water, assess and manage the ABCs and contact a paramedic crew to intervene if needed. Administer oxygen at 100% via a non-rebreathing mask or bag-mask device if assisted

ventilations are required. Be prepared to apply suction, given that these patients often vomit. If trauma is suspected, apply a cervical collar and place the child on a backboard. Pad all open spaces under the pediatric patient before securing the patient onto the backboard. If the pediatric patient is unresponsive and in cardiopulmonary arrest, perform CPR beginning with chest compressions.

Safety

Before using an AED on a pulseless drowning patient, ensure that the patient is dried off first. Use extreme caution when operating an AED in this situation.

Pediatric Trauma Emergencies and Management

Trauma is the number one cause of death of children in the United States.²³ As an AEMT, you will frequently treat injured children; therefore, you must have a thorough understanding of how trauma affects them. The quality of care in the first few minutes after a child has been injured can have an enormous effect on that child's chances for complete recovery.

Infants and toddlers are most commonly hurt as a result of unintentional suffocation, drowning, falls, or abuse.²² According to the CDC, motor vehicle crashes, including those involving bicycles and pedestrians, are the most significant threat to the well-being of children ages 5 years and older.²⁴ Other common causes of traumatic injury and death include falls, gunshot wounds, blunt injuries, and sports activities.

Psychological Differences

Children are less mature psychologically than adults; therefore, they are often injured because of their undeveloped judgment and their lack of experience. For example, children are more likely than adults to cross the street without looking for oncoming traffic. As a result, children are more likely than adults to be struck by motor vehicles. Children and adolescents are also more likely to sustain injuries from diving into shallow water because they forget to check the depth of the water before they dive. In such situations, always assume that the child has serious head and neck injuries.

Physical Differences

Children are smaller than adults; therefore, when they are hurt in the same type of crash as an adult, the location of their injuries may differ from those in an adult. For example, the bumper of a motor vehicle will strike an adult pedestrian in the lower leg, whereas that same bumper will strike a child in the pelvis. In a crash involving sudden deceleration, an adult might injure a ligament in the knee; in that same accident, a child might injure the bones in the leg.

The younger the child, the more flexible the bone structures are to trauma. Children's bones and soft tissues are less well developed than those of adults; therefore, the force of an injury affects these structures somewhat differently than it does in an adult. Because a child's head is proportionately larger than an adult's, it exerts greater stress on the neck structures during a deceleration injury. Because of these anatomic differences, you should always carefully assess children for head and neck injuries.

Words of Wisdom

The XABCDE mnemonic reminds us that the first critical step for any trauma patient is controlling exsanguinating hemorrhage. The use of tourniquets is especially effective for extremity hemorrhage. Shortly after the active shooter incident at Sandy Hook Elementary School that occurred on December 14, 2012 in Newtown, Connecticut, the American College of Surgeons (ACS) convened a committee of representatives from many organizations to create a national policy to enhance survivability. This effort was based on autopsy reports that many children at Sandy Hook died of extremity hemorrhage that could have been successfully controlled with the placement of tourniquets. The nationwide Stop the Bleed campaign is another result that came about as an outcome of the committee findings. See Chapter 27, *Bleeding*, for more information.

Injury Patterns

Although you are not responsible for diagnosing injuries in children, your ability to recognize and report serious injuries will provide critical information to hospital staff. For this reason, it is important for you to understand the special physical and psychological characteristics of children and what makes them more likely to have certain kinds of injuries.

Vehicle Collisions

Children playing or riding a bicycle can dart out in front of motor vehicles without looking. In such a situation, the driver may have little time to slow down or stop to prevent hitting the child. The area of greatest injury varies, depending on the size of the child and the height of the bumper at the time of impact. When vehicles slow down at the moment of impact, the bumper dips slightly, causing the point of impact with the child to be lowered. The exact area that is struck depends on the child's height and the final position of the bumper at the time of impact. Children who are injured in these situations often sustain high-energy injuries to the head, spine, abdomen, pelvis, or legs. In addition to differences in size and anatomy, children will often turn toward an oncoming vehicle when they see it approaching and, therefore, sustain different injuries than an adult who turns away.

Injuries to Specific Body Systems

Head Injuries

Head injuries are common in children. This is because the size of a child's head, in relation to the body, is larger than that of an adult. An infant also has a softer, thinner skull, which may result in injury to the underlying brain tissues. The scalp and facial vessels can bleed easily and may cause a great deal of blood loss if the bleeding is not controlled.

The signs and symptoms of head injury in a child are similar to those in an adult, but there are some important differences. Nausea and vomiting are common signs and symptoms of head injury in children; however, it is easy to mistake these for an abdominal injury or illness. You should suspect a serious head injury in any child who experiences nausea and vomiting after a traumatic event. Pediatric patients are managed in the same manner as adults. Chapter 30, *Head and Spine Injuries*, discusses head injuries in detail.

Immobilization

Spinal immobilization is necessary for all children who have possible head or spinal injuries after a traumatic event.

To immobilize a pediatric patient on a short backboard or pediatric immobilization device, follow the steps in **SKILL DRILL 36-6**.

Skill Drill 36-6 Immobilizing a Pediatric Patient

Step 1

Maintain the child's head in a neutral position by placing a towel under the torso, from the shoulders to the hips.

Step 2

Apply an appropriate-size cervical collar.

Step 3

Log roll the child onto the short backboard or pediatric immobilization device.

Step 4

Secure the pediatric patient's torso to the short backboard or pediatric immobilization device first.

Step 5

Secure the child's head to the short backboard or pediatric immobilization device.

Step 6

Ensure that the child is strapped in properly.

Immobilization can be difficult to perform because of the child's body proportions. Young children require padding under the torso to maintain a neutral position. At approximately 8 to 10 years of age, children no longer require padding underneath the torso to create a neutral position. Instead, they can simply lie supine on the backboard. However, another complication may occur if a child is put onto an adult-size backboard. Because a child's body is narrower than an adult's, padding will be required along the sides so that the child can be properly secured on an adult-size backboard. If using an adult-size backboard, make sure to slide the child all the way up to the head of the backboard.

Many infants and children will be in a car seat when you approach them. There are two methods of transportation that are determined by the severity of the pediatric patient's condition. If the pediatric patient has stable vital signs, minimal injury, and the car seat is visibly undamaged, the patient may be left in the seat. Ensure that the patient is secured within the seat and the seat is secured in the ambulance for transportation. If the pediatric patient

is unstable, has injuries other than minor ones, or the car seat is visibly damaged, the child must be removed from the car seat and immobilized on a short backboard or pediatric immobilization device prior to transport.

Ideally, a cervical collar would be used when immobilizing an infant or toddler; however, an appropriate-size cervical collar may not be available. In this case, place rolled towels on either side of the head to prevent side-to-side movement. Do not place a towel in the shape of an upside-down "U" over the pediatric patient's head; this may press down on the head and compromise the airway and spinal cord. The steps for removing a pediatric patient from a car seat and immobilizing the patient on a short backboard or pediatric immobilization device are shown in **SKILL DRILL 36-7**.

Chest Injuries

Chest injuries in children are usually the result of blunt trauma rather than penetrating objects. Remember that children have extremely soft, flexible ribs that can be substantially compressed without

Skill Drill 36-7 Immobilizing a Patient Found in a Car Seat

Step 1

Carefully stabilize the patient's head in a neutral position. Leave all car seat straps in place.

Step 2

Lay the car seat down into a reclined position on a hard surface. Position a short backboard or pediatric immobilization device between the patient and the surface on which the patient is resting.

Step 3

Slide the patient into position on the short backboard or pediatric immobilization device. Remove the patient and device from the car seat as one unit.

Skill Drill 36-7 Immobilizing a Patient Found in a Car Seat (continued)

Step 4

Place a towel under the back, from the shoulders to the hips, to ensure neutral head position.

Step 5

Secure the torso first and place padding to fill any voids.

Step 6

Secure the patient's head to the short backboard or pediatric immobilization device.

breaking. Keep this in mind as you assess a child who has sustained high-energy blunt trauma to the chest. Although there may be no external sign of injury such as broken ribs, contusions, or bleeding, there may be significant injuries within the chest (**FIGURE 36-34**). Pediatric patients with chest injuries are managed in the same manner as adults. Chapter 31, *Chest Injuries*, discusses the treatment of chest injuries in detail.

Abdominal Injuries

Abdominal injuries are common in children. Remember, though, that children can compensate for substantial blood loss better than adults without signs or symptoms of shock developing (**FIGURE 36-35**). Children can also have a serious injury without early external evidence of a problem. All children with abdominal injuries should be monitored for signs and symptoms of shock, including a weak, rapid pulse; cold, clammy skin; decreased capillary refill (an early sign); confusion; and decreased systolic blood pressure (a late sign). Even in the absence of signs and symptoms of shock, or with only a few signs and symptoms,

FIGURE 36-34 A child's ribs are softer and more flexible than an adult's. As a result, the ribs may compress the lungs and heart if there is blunt trauma, causing serious injury with no obvious external damage.

© Jones & Bartlett Learning.

you should remain cautious about the possibility of internal injuries.

Pediatric patients with abdominal injuries are treated in the same manner as adults. If the patient

FIGURE 36-35 All children with abdominal injuries should be monitored closely for signs of shock. Although children may compensate for significant blood loss better than adults, shock develops in children after proportionally smaller blood losses.

© Jones & Bartlett Learning.

shows signs and symptoms of shock, prevent hypothermia by keeping the patient warm with blankets. If the patient has bradycardia, ventilate. Monitor the patient's condition during transport. Chapter 32, *Abdominal and Genitourinary Injuries*, discusses abdominal injuries in detail.

Injuries of the Extremities

Children have immature bones with active growth centers. Growth of long bones occurs from the ends at specialized growth plates. These growth plates, or epiphyseal plates, are potential weak spots in the bone and are often injured as a result of trauma. In general, children's bones bend more easily than those of an adult. As a result, incomplete, or greenstick fractures can occur.

Extremity injuries in children are generally managed in the same manner as those in adults. Painful, deformed limbs with evidence of broken bones should be splinted. Specific splinting equipment, such as a traction splint for fractures of the femur, should be used only if it fits the child. Do not attempt to use adult immobilization devices on a child unless the child is large enough to properly fit in the device. Chapter 33, *Orthopaedic Injuries*, discusses extremity injuries.

Burns

Burns to children are generally considered more serious than burns to adults. This is because infants and children have more body surface area relative to their total body mass, which means greater fluid

FIGURE 36-36 The most common burns in children involve exposure to hot surfaces. This child's buttocks were placed against a hot heating grate. The severity and cause of this burn raise the concern of abuse.

© Charles Stewart MD, EMDM MPH.

and heat loss. In addition, children do not tolerate burns as well as adults do. Hypothermia is more likely to develop, and children may go into shock and experience airway problems because of the unique differences related to age and anatomy.

Children can be burned in a variety of ways. The most common incidents involve exposure to hot substances such as scalding water in a bathtub, or hot items on a stove, or exposure to caustic substances such as cleaning solvents or paint thinners (**FIGURE 36-36**). You should suspect possible internal injuries from chemical ingestion when you see a child who has burns around the face and mouth.

One common problem following burn injuries in children is infection. Burned skin cannot resist infection as effectively as normal skin can. For this reason, sterile techniques should be used in handling the skin of children with burn wounds, if possible.

TABLE 36-14 provides some general guidelines to follow in assessing a child who has been burned. These guidelines may help you to determine which children should be treated primarily at specialized burn centers. Always consider the possibility of abuse in any burn situation.

Treat a pediatric burn patient as you would an adult burn patient. Obtain vascular access, preferably in a nonburned area, and administer 20-mL/kg boluses of NS or lactated Ringer solution if the child is in shock. Keep the patient warm. If the patient has

TABLE 36-14 Severity of Burns in Pediatric Patients

Severity of Burn	Body Area Involved
Minor	Partial-thickness burns involving less than 10% of the body surface
Moderate	Partial-thickness burns involving 10% to 20% of the body surface
Critical	Any full-thickness burn Any partial-thickness burn involving more than 20% of the body surface Any burn involving the hands, feet, face, airway, or genitalia

© Jones & Bartlett Learning.

bradycardia, ventilate. Reassess the child's condition and administer additional IV fluids as needed. Chapter 28, *Soft-Tissue Injuries*, discusses burn care in detail.

Insert an IO catheter if you are unable to obtain IV access after three tries or 90 seconds, as determined by local protocols.

Fluid Management

Circulatory compromise is less common in children than in adults as the result of trauma; therefore, airway management and ventilatory support take priority over management of circulation. Consider the following when you are establishing vascular access in the injured child:

- Large-bore IV catheters should be inserted into a large peripheral vein whenever possible.
- Because definitive care can only be provided at the hospital, never delay transport for the purpose of starting an IV line; this procedure should be performed en route to the hospital.
- To maintain perfusion in a child, administer an initial bolus of 20 mL/kg using an isotonic crystalloid solution (ie, NS, lactated Ringer solution).
 - Frequently reassess the child's vital signs and provide additional IV fluid boluses of 20 mL/kg if no improvement is noted following the initial bolus.
 - If the child's condition does not improve following two boluses of an isotonic

crystalloid, blood loss is likely severe and will probably need surgical intervention. Provide rapid transport with continuous monitoring of the child en route.

If IV access cannot be obtained within three attempts or 90 seconds, insert an IO needle to gain access to the vascular system.

Pain Management

The first step in pain management is recognizing the patient is in pain. Some patients will be non-verbal or have a limited vocabulary. Look for visual clues and use the Wong-Baker FACES pain scale (see Figure 36-16).

When dealing with pediatric pain management issues, you are limited to the following interventions: positioning, ice packs, extremity elevation, and nitrous oxide administration as allowed by local protocols. These interventions will decrease the pain and swelling to the site of an injury. However, additional interventions (medications) from a paramedic provider may be necessary. Another important tool is simple kindness and providing emotional support to the patient and the parent or caregiver. This act alone can decrease anxiety and allow for a more soothing environment for all involved. Children can sense fear and frustration from adults, so it is important to maintain a calm, professional, and trusting relationship with your patient and the family during the course of treatment.

Disaster Management

The JumpSTART triage system was developed for pediatric patients because the original START triage system did not account for the developmental and physiologic differences in children (**FIGURE 36-37**). This system is intended for pediatric patients younger than age 8 years or who appear to weigh less than 100 pounds (45 kg). Because infants and children may not be able to walk or follow commands during a disaster event, they must be considered for immediate delivery to the treatment area.

There are four triage categories in the JumpSTART system, designated by colors corresponding to different levels of urgency for treatment. Decision points include ability to walk (except in infants), presence of spontaneous breathing, respirations of less than 15 or greater than 45 breaths/min, palpable

FIGURE 36-37 The JumpSTART triage system.

Abbreviation: AVPU, Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive

© Lou Romig MD, 2002.

peripheral pulse, and appropriate response to painful stimuli on the AVPU scale.

Pediatric patients who are able to walk are designated as the third or minor priority (green tag), meaning they are not in immediate need of treatment. Those patients breathing spontaneously, with a peripheral pulse and appropriately responsive to painful stimuli, are considered second priority (yellow tag). Their treatment and transport can be delayed. Pediatric patients who are apneic and responsive to positioning or rescue breathing; who are in respiratory failure; who are breathing but pulseless; or who are inappropriately responsive to painful stimuli are considered highest priority (red tag). Pediatric patients who are both apneic

and pulseless, or who are apneic and unresponsive to rescue breathing, are considered deceased or expectant deceased (black tag).

Child Abuse and Neglect

The term **child abuse** means any improper or excessive action that injures or otherwise harms a child or infant; it includes physical abuse, sexual abuse, neglect, and emotional abuse. The intentional injury of a child, whether physical or emotional, is not rare in our society. Each year in the United States, nearly 700,000 children are abused.²⁵ Many of these children sustain life-threatening injuries, and some die. If suspected child abuse is not reported, the child is likely to be abused again and again, perhaps sustaining permanent injuries or even death. Therefore, you must be aware of the signs of child abuse and neglect, and of your responsibility to report suspected abuse to law enforcement or child protection agencies.

Signs of Abuse

As an AEMT, you will be called to homes because of a reported injury to a child. Child abuse occurs in every socioeconomic status, so be aware of the patient's surroundings and document your findings objectively. AEMTs are often called to testify in abuse cases, so it is essential to record all findings, including any statements made by parents or caregivers or others on the scene. If you suspect that physical or sexual abuse is involved, ask yourself the following questions:

- Is the injury typical for the developmental level of the child?
- Is the method of injury reported by the parent or caregiver consistent with the child's injuries?
- Is the parent or caregiver behaving appropriately (concerned about the child's well-being)?
- Is there evidence of drinking or drug use at the scene?
- Was there a delay in seeking care for the child?
- Is there a good relationship between the child and the parent or caregiver?
- Does the child have multiple injuries at different stages of healing?
- Does the child have any unusual marks or bruises that may have been caused by cigarettes, heating grates, or branding injuries?
- Does the child have several types of injuries, such as burns, fractures, and bruises?
- Does the child have any burns on the hands or feet that involve a glove distribution (marks that encircle a hand or foot in a pattern that looks like a glove)?
- Is there an unexplained decreased level of consciousness?
- Is the child clean and an age-appropriate weight?
- Is there any rectal or vaginal bleeding?
- What does the home look like? Clean or dirty? Is it warm or cold? Is there adequate food?

Your assessment in the field will allow a better assessment by the medical staff later. An easy way to remember these is the mnemonic CHILD ABUSE shown in **TABLE 36-15**.

As you assess the pediatric patient, look for and pay particular attention to the following signs (**FIGURE 36-38**).

Bruises

Observe the color and location of any bruises. New bruises are pink or red. Over time, bruises turn blue, then green, then yellow-brown and faded. Note the location. Bruises to the back, buttocks, ears, or face are suspicious and are usually inflicted by someone else.

TABLE 36-15 CHILD ABUSE Mnemonic for Assessing Possible Child Abuse

C Consistency of the injury with the child's developmental age
H History inconsistent with injury
I Inappropriate parental concerns
L Lack of supervision
D Delay in seeking care
A Affect (of the parent or caregiver and the child in relation to the caregiver)
B Bruises of varying ages
U Unusual injury patterns
S Suspicious circumstances
E Environmental clues

**A****B**

FIGURE 36-38 Signs of child abuse. **A.** A scald injury. **B.** Multiple injuries at different stages of healing.

Courtesy of Ronald Dieckmann, MD.

Burns

Burns to the penis, testicles, vagina, or buttocks are usually inflicted by someone else, as are burns that encircle a hand or foot to look like a glove. You should suspect abuse if the child has cigarette burns or grid pattern burns.

Fractures

Fractures of the humerus or femur do not normally occur without major trauma, such as a fall from a high place or a motor vehicle crash. Falls from bed are not usually associated with fractures. You should maintain some index of suspicion if an infant or young child sustains a femur fracture or a complete fracture of any bone.

Shaken Baby Syndrome

Infants may sustain head trauma by being shaken or struck on the head, a life-threatening condition called **shaken baby syndrome**. With this condition, there is bleeding within the head and damage to the cervical spine as a result of intentional, forceful shaking. The infant will be found unresponsive, often without evidence of external trauma. The

call for help may be for an infant who has stopped breathing or is unresponsive. The infant may appear to be in cardiopulmonary arrest, but what has likely occurred is that the shaking tore blood vessels in the brain, resulting in bleeding around the brain. The pressure from the blood results in increased cranial pressure, leading to coma and/or death.

Neglect

Neglect is refusal or failure on the part of the parent or caregiver to provide life necessities, such as food, water, clothing, shelter, personal hygiene, medicine, comfort, and personal safety.

Children who are neglected are often dirty or too thin or appear developmentally delayed because of lack of stimulation. You may observe such children when you are making calls for unrelated problems. Report all cases of suspicious neglect.

Symptoms and Other Indicators of Abuse

An abused child may appear withdrawn, fearful, or hostile. Be particularly concerned if the child refuses to discuss how an injury occurred. Occasionally,

the parent or caregiver will reveal a history of several “accidents.” Be alert for conflicting stories or a marked lack of concern from the parents or caregiver. Remember, the abuser may be a parent, caregiver, relative, or friend of the family. Sometimes the abuser is an acquaintance of a single parent.

AEMTs in all states must report all cases of suspected abuse, even if the ED fails to do so. Most states have special forms for reporting. Supervisors are generally forbidden from interfering with the reporting of suspected abuse, even if they disagree with the assessment. You do not have to prove that there has been abuse. Law enforcement and child protection agencies are mandated to investigate all reported cases. Take all necessary precautions to protect yourself, your team, and the pediatric patient involved in this situation.

Sexual Abuse

Children of any age and either sex can be subjected to sexual abuse. According to the Department of Health and Human Services, approximately 8.4% of child abuse cases reported are sexual abuse.²⁶ Among children, the most likely victims of rape and sexual assault are females aged 16 to 19 years.²⁷ However, males and younger children may be victims as well. This type of abuse is often the result of long-standing abuse by relatives.

Your assessment of a child who has been sexually abused should be limited to determining the type of dressing any injuries require. Sometimes, a sexually abused child is also beaten. Therefore, treat any bruises or fractures as well. Do not examine the genitalia of a young child unless there is evidence of bleeding or there is an injury that must be treated.

In addition, if you suspect that a child has been subjected to sexual abuse, do not allow the child to wash, urinate, or defecate before a physician completes an examination. Although this step can be difficult for the patient, it is important to preserve evidence. If possible, ensure that an AEMT or police officer of the same gender remains with the child, unless locating one will delay transport.

You must maintain professional composure the entire time you are assessing and caring for a sexually abused child. Assume a concerned, caring demeanor, and shield the child from onlookers and curious bystanders. Obtain as much information as possible from the child and any witnesses. The child

may be hysterical or unwilling to say anything at all, especially if the abuser is a relative or family friend. You are in the best position to obtain the most accurate firsthand information about the incident. Therefore, record any information carefully and completely on the patient care report. Transport all children who are victims of sexual assault. Sexual abuse of a child is a crime. Cooperate fully with law enforcement officials in their investigations.

Death of a Child

The death of a child from any cause poses special challenges for EMS personnel. In addition to any medical treatment the child may require, you must be prepared to offer the family a high level of support and understanding as they begin the grieving process. First, the family may want you to initiate resuscitation efforts, which may or may not conflict with your EMS protocols. If the child is clearly deceased and, under protocol, can be declared dead in the field, but the family is so distraught that they insist that resuscitation efforts be made, initiate CPR and transport the child.

Again, coping with the death of a child can be highly stressful for health care professionals. You may find yourself with unexpected feelings of pain and loss. It is helpful to take some time before going back on the job to work through your feelings and to talk about the event with your EMS colleagues. Be alert for signs of posttraumatic stress in yourself and others: nightmares, restlessness, difficulty sleeping, lack of appetite, or a constant need for food, and the like. Consider the need for professional help if these signs or symptoms continue. Some EMS programs have found it helpful to have critical incident stress management (CISM) protocols and defusing and debriefing teams available for traumatic incidents. For more information about defusing, debriefing,

Street Smarts

Some EMS systems arrange for home visits after the death of a child so that EMS providers and family members can come to some sort of closure together. This also gives the family an opportunity to ask any remaining questions about the event. However, you need special training for such visits. This can be a session with a trained counselor or a group discussion with your colleagues or the entire health care team.

and CISM programs, see Chapter 2, *Workforce Safety and Wellness*.

Although you may experience the death of a child as a failure, your skill at coping with this kind of emotional event can be a great comfort to the family, helping them to accept their loss and begin the long process of grieving.

Sudden Infant Death Syndrome

The unexpected death of an infant or young child is called **sudden infant death syndrome (SIDS)** when, after a complete autopsy, the cause of death remains unexplained. In 2018, approximately 1,300 infant deaths were attributed to SIDS.²⁸

Although it is impossible to predict SIDS, there are several known risk factors:²⁹

- The mother smoked during pregnancy or anyone smokes around the infant
- Low birth weight
- The baby is placed on the stomach in a crib or on soft surfaces with loose bedding

Deaths as the result of SIDS can occur at any time of the day; however, these children are often discovered in the morning when the parents or caregivers go in to check on the infant. If you are the first provider at the scene of suspected SIDS, you will face three tasks: assessment of the scene, assessment and management of the patient, and communication and support of the family.

Scene Assessment

Carefully inspect the environment, following local protocols, noting the condition of the scene where the caregivers found the infant or young child. Your assessment of the scene should concentrate on the following:

- Signs of illness, including medications, humidifiers, or thermometers
- The general condition of the house
- Signs of poor hygiene
- Family interaction. Do not allow yourself to be judgmental about family interactions at this time. Note and report any behavior that is clearly not within the acceptable range, such as physical and verbal abuse.
- The site where the child was discovered. Note all items in the child's crib or bed, including pillows, stuffed animals, toys, and small objects.

Assessment and Management of SIDS

SIDS is a diagnosis of exclusion. All other potential causes must first be ruled out, a process that may take physicians a lot of time. An infant who has died of SIDS will be pale or blue, not breathing, pulseless, and unresponsive. Other causes for such a condition include the following:

- Accidental suffocation or strangulation in bed
- Overwhelming infection
- Child abuse
- Airway obstruction from a foreign object or as a result of infection
- Meningitis
- Accidental or intentional poisoning
- Hypoglycemia (low blood glucose level)
- Congenital metabolic defects

Regardless of the cause, assessment and management of the infant remain the same. Remember that what you find in assessing the infant and the scene may provide important diagnostic information.

Begin with an assessment of the ABCDEs and provide interventions as necessary. Depending on how much time has passed since the child was discovered, the child may show signs of postmortem changes. These include stiffening of the body, called rigor mortis, and dependent lividity, which is the pooling of blood in the lower parts of the body or those that are in contact with the floor or bed.

If the child shows such signs, call medical control. In some EMS systems, a victim of SIDS may be declared dead on the scene. Deciding whether to start CPR on a child who shows clear signs of rigor mortis or dependent lividity can be difficult. Family members may consider anything less as withholding critical care. In this situation, the best course of action may be to initiate CPR, beginning with chest compressions, and transport the patient and the family to the nearest ED, where the family can receive more extensive support (follow local protocols). If there is no evidence of postmortem changes, begin CPR immediately. Chapter 15, *BLS Resuscitation*, covers providing CPR to pediatric patients in detail.

As you assess the infant, pay special attention to any marks or bruises on the child before performing any procedures, including CPR. Also note any intervention such as CPR that was done by the parents before you arrived.

Communication and Support of the Family

The extent of your interaction with the family will depend, to some degree, on the number of providers available at the scene. Always introduce yourself to the child's parents or caregivers and ask the child's name, date of birth, and medical history. If and when the decision is made to start or stop resuscitation efforts, inform the family immediately. Find a place for family members where they can watch resuscitation without being in the way. Do not, in any case, speculate on the cause of the child's death. The family will want to see the child and should be asked whether they want to hold the child and say good-bye. Parents or caregivers may be experiencing strong feelings of denial.

Remember that each individual and each culture expresses grief in a different way, some more visibly than others. Some will require intervention; others will not. Most parents or caregivers feel directly or indirectly responsible for the death of a child and may express this immediately; this does not mean that they actually are responsible. Although you should keep the possibility of abuse or neglect in mind, your role is not that of investigator. Any further inquiry is the responsibility of law enforcement.

Part of your job at this point is to allow the family to express their grief in ways that may differ from your own cultural, religious, and personal practices. Provide support in whatever ways you can (**TABLE 36-16**).

TABLE 36-16 How You Can Help the Family of a Deceased Child

When arriving on site	Introduce yourself quickly. Speak to family members at eye level, maintaining good eye contact with them. Obtain a brief history. When possible, one provider should stay with the family. Ask the child's name and refer to the child by that name.
If resuscitation is attempted	Give brief, frequent updates and explanations. Allow family members to stay within viewing distance if they wish. Allow family members to accompany the child to the hospital when possible.
If no resuscitation is performed	Sit down with the family. Inform the family immediately. Explain why no resuscitation will be attempted. Offer to arrange for religious support, including baptism or last rites.
Beginning the grieving process	Cover the child in a blanket. Learn and use the child's name. Allow the family to express emotions; be nonjudgmental. Offer to call other family members. Give brief explanations and answers. Acknowledge the family's feelings ("I know this is devastating for you"). Use the word "dead" or "died" when informing the family of the child's death. Explain to the family that the cause of death is still unknown. Allow time for questions.
Do	Tell the family how sorry you are. Tell the family whom they can call if they have questions later. Give written instructions and referrals.
Do not	Say, "You have other children," or "You can have other children." Attempt to answer the question "Why did this happen?" Try to tell the family that they will feel better with time. Use euphemisms such as "passed away" or "gone." Say, "I know how you feel," even if you have experienced a similar event.

TABLE 36-17 Common Questions Following Death of a Child**Q:** Was there pain?**A:** This often can be answered by a simple “No.” If you are uncertain, you may give an indirect answer such as, “We really don’t know what patients feel in these circumstances.”**Q:** What did the child die of?**A:** Do not answer this question; you would probably be guessing.**Q:** Why did this happen?**A:** Do not attempt to answer this question either because the answer depends on one’s own individual philosophy or religion. “I wish I had an answer for you” is usually the most appropriate response.**Q:** What happens now?**A:** This question usually concerns the next few minutes or the next hour. If you know, you should give the family a general idea of what will happen. For example, if there is no history of illness, you can say, “A medical examination will be done, and then [the child’s name] will be taken to the mortuary.”

© Jones & Bartlett Learning.

Parents often have questions that you should be prepared to answer: Why did this happen? How did this happen? Let them know that their concerns will be addressed but that answers are not immediately available (**TABLE 36-17**). Always use the child’s name in speaking to family members. If possible, allow the family to spend time with the child and to ride in the ambulance to the hospital.

Brief Resolved Unexplained Event

Infants who are not breathing and are cyanotic and unresponsive when found by their families sometimes resume breathing and color with stimulation. These children have had what is called a

brief resolved unexplained event (BRUE), called “near-miss SIDS” in the past. In addition to cyanosis and apnea, a classic BRUE is characterized by a distinct change in muscle tone (limpness) and choking or gagging. After the event, a child may appear healthy and show no signs of illness or distress. Nevertheless, you must complete a careful assessment and provide immediate transport to the ED.

Pay strict attention to management of the airway. Assess the infant’s history and, if possible, the environment. Allow caregivers to ride in the ambulance. If asked, explain that you cannot say what caused the event and that this is something that the physician will have to determine at the hospital.

YOU are the Provider SUMMARY

1. What stage of growth and development is this child in, and what are some of the key milestones that you can anticipate seeing?

This 5-year-old child is categorized as a preschool-age child. When they are responsive, you should expect children of this age range to use simple language effectively and have a lively imagination. Also, they can understand directions, are able to be specific in describing their sensations, and identify painful areas when asked.

2. When treating an infant or pediatric patient, what is often the best source of information regarding the current condition?

Depending on the age of the pediatric patient and level of responsiveness, the child may or may not be able to provide you with information needed to make treatment decisions. Furthermore, younger children often cannot tell you where they hurt. Therefore, you must rely on a parent or caregiver to obtain as much information as you can.

3. What is the purpose of the PAT, and what does it assess?

The PAT is a structured assessment tool that allows you to rapidly form a general impression of the patient's condition without touching the child. It is intended to provide a "first-glance" assessment to help you identify the general category of the child's physiologic problem and to establish the urgency for treatment and/or transport. The PAT assesses three elements: appearance, work of breathing, and circulation to the skin.

4. When should an oropharyngeal airway be inserted in a pediatric patient, and how is it measured?

An oropharyngeal airway should be inserted in the pediatric patient any time the patient is unresponsive and cannot maintain their own airway spontaneously. The oropharyngeal airway is measured from the corner of the patient's mouth to the earlobe (on the same side) or by using a length-based resuscitation tape to measure the patient.

5. What are normal vital signs for a patient of this age?

"Normal" vital signs are going to vary depending on the state of the child and the techniques used to obtain them. After ensuring that you are using appropriate-size equipment, and explaining

to the patient step-by-step what you are going to do, the generally accepted respiratory rate for a preschool-age child is 20 to 28 breaths/min, the pulse should be between 65 and 120 beats/min, and the systolic blood pressure should be between 89 and 112 mm Hg. It is important to remember that blood pressure should not be obtained in children younger than 3 years in the prehospital setting.

6. What is the purpose of a Volutrol?

A Volutrol is a special type of macrodrip set that allows you to fill the large drip chamber with a specific amount of fluid and administer only that amount. The 100-mL drip chamber on the Volutrol can be isolated from the IV bag, preventing fluid overload.

7. How should the glucose be prepared?

Glucose administration in pediatric patients age 1 year and older should be accomplished with D₂₅ or D₁₀ instead of D₅₀. Because of the thickness of D₅₀, there is a greater potential of extravasation, and subsequent tissue necrosis. If your service does not routinely stock D₂₅, it can be easily made from D₅₀. To make D₂₅, you should replace 25 mL of the D₅₀-prefilled syringe with 25 mL of NS, resulting in a concentration of D₂₅. To make D₁₀, you should draw 4 mL from the D₅₀-prefilled syringe into a 20-mL syringe and add an additional 16 mL of NS.

8. What are the indications and contraindications for dextrose administration in pediatric patients?

The indications for dextrose administration in pediatric patients are the same as with adult patients, to include symptomatic bradycardia, altered level of consciousness for unknown reasons, unresponsiveness with unknown patient history, and a coma of unknown etiology.

Contraindications for dextrose administration include the presence of increased intracranial pressure or possible intracranial bleeding.

9. If this patient should require IV fluid, how much fluid should she receive?

Fluid resuscitation for this patient should begin with an initial bolus of 20 mL/kg, which is a 360-mL bolus for this patient because she weighs 18 kg (39 lb), followed by careful reassessment. Additional fluid boluses of 20 mL/kg may be administered as needed to maintain adequate perfusion.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 10-7-21	Incident No.: 0103	Nature of Call: Unresponsive		Location: 424 N. Cavalier Street	
Dispatched: 1255	En Route: 1302	At Scene: 1309	Transport: 1318	At Hospital: 1335	In Service: 1400

Patient Information

Age: 5	Allergies: None
Sex: F	Medications: None
Weight (in kg [lb]): 18 kg (39 lb)	Past Medical History: None
	Chief Complaint: Unresponsive, possible overdose

Vital Signs

Time: 1310	BP: Not obtained	Pulse: Not obtained	Respirations: 4-A	Spo₂: Not obtained
Time: 1317	BP: Unable to obtain	Pulse: 155	Respirations: 20-A	Spo₂: 99% on 15 L/min
Time: 1333	BP: 90/P	Pulse: 130	Respirations: 30	Spo₂: 99% on 15 L/min

EMS Treatment (circle all that apply)

Oxygen @ 15 L/min via (circle one): NC NRM Bag-mask device		Assisted Ventilation: Yes	Airway Adjunct: OPA	CPR
Defibrillation	Bleeding Control	Bandaging	Splinting	Other: Medication administration

Narrative

EMS dispatched to above location for unresponsive child. Met at door of residence by elderly man who directs us to patient found in back bedroom. Patient found supine on bed, unresponsive, with agonal respirations. Mother states that patient possibly got into some diabetes medication in the house. Airway established with OPA and ventilations assisted via bag-mask device with oxygen. PAT—poor. Once ventilations established, patient placed on stretcher, secured, and placed in back of ambulance. Dispatch contacted for paramedic transport, advised no units available. Vital signs as above, blood glucose obtained at 26 mg/dL. IV established with 22-gauge catheter on Volutrol. Emergency transport initiated. Verified patency, administered 90 mL D₁₀. On recheck of blood glucose level, found to be 134 mg/dL with patient beginning to breathe more effectively, with some purposeful movement. Patient placed on 15 L/min via NRB. Patient crying for mother. Transport stopped, mother secured in back of ambulance to calm patient. Transport resumed nonemergency. On arrival at ED, patient acting appropriate for age, in no acute distress. Care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- Children are not only smaller than adults and more vulnerable, they are also anatomically, physiologically, and psychologically different from adults in some important ways.
- General rules for caring for pediatric patients of all ages include appearing confident, being calm, remaining honest, and keeping parents or caregivers together with the pediatric patient as much as possible.
- Infancy is the first year of life. If possible, allow the parent or caregiver to hold the infant during the assessment.
- The toddler is 1 to 3 years of age. Toddlers may experience stranger anxiety but may be able to be distracted by a special object (blanket) or toy.
- Preschool-age children are 3 to 6 years of age. Preschool-age children can understand directions and can identify painful areas when questioned. Tell these children what you are going to do before you do it. This action can help prevent the development of frightening fantasies.
- School-age children are 6 to 12 years of age. These children are familiar with the physical examination process. Talk about their interests to distract them during a procedure.
- Adolescents are 12 to 18 years of age. Respect the adolescent's modesty. Remember that even though this age group is physically similar to adults, adolescents are still children on an emotional level.
- The growing bodies of pediatric patients create some special considerations.
- The tongue is large relative to other structures, so it poses a higher risk of airway obstruction than in an adult.
- An infant breathes faster than an older child. Breathing requires the use of chest muscles and the diaphragm.
- The airway in a child has a smaller diameter than the airway in an adult and is therefore more easily obstructed.
- A rapid heartbeat and blood vessel constriction help pediatric patients to compensate for decreased perfusion.
- Children's internal organs are not as insulated by fat as in adults and may be injured more severely. Also, children have less circulating blood than adults, so although they exhibit the signs of shock more slowly they go into shock more quickly, with less blood loss.
- Children's bones are more flexible and bend more with injury; the ends of the long bones, where growth occurs, are weaker and may be injured more easily.
- Because a young child might not be able to speak, your assessment of the child's condition must be based largely on what you can see and hear yourself. Families may be helpful in providing vital information about an accident or illness.
- Use the PAT to obtain a general impression of the infant or child. Use the AVPU scale or the Pediatric Glasgow Coma Scale to assess a pediatric patient's level of consciousness.
- You will need to carry special sizes of airway equipment for pediatric patients. Use a length-based resuscitation tape to help determine the appropriate size of equipment for children.
- The three keys to successful use of the bag-mask device in a child are: (1) have the appropriate equipment in the right size; (2) maintain a good face-to-mask seal; and (3) ventilate at the appropriate rate and volume.
- You must intervene immediately if bradycardia develops in a child in respiratory distress,

providing oxygenation and assisted ventilations if they become necessary.

- Signs of shock in children are tachycardia, poor capillary refill time, and mental status changes. You must be extremely alert for signs of shock in pediatric patients because they can decompensate rapidly.
- Appropriate fluid administration in the pediatric patient is crucial; IV fluids must be administered based on the child's clinical condition.
- IV therapy is not performed as frequently in children as it is in adults, but the technique, indications, and contraindications in the infant and child are the same as they are for adults.
- Fluid control for pediatric patients is important. Using a special type of microdrip set allows you to administer a specific amount of fluid.
- When possible, allow the infant or child to sit on the parent or caregiver's lap when starting the IV line.
- IO infusion is used for emergency vascular access in pediatric patients as defined by protocol when immediate IV access is difficult or impossible. As a general guideline, an IO insertion should be attempted if you are unable to obtain IV access within three attempts *or* 90 seconds or based on local protocols in a critically ill or injured pediatric patient.
- An IO infusion is contraindicated if a secure IV line is available or if a possible fracture exists in the same bone in which you plan to insert the IO needle.
- Establish vascular access in any infant or child in shock; administer 20-mL/kg boluses of NS or lactated Ringer solution as needed to maintain adequate perfusion.
- Febrile seizures may be a sign of a more serious problem such as meningitis.
- The most common cause of dehydration in children is vomiting and diarrhea. Life-threatening diarrhea can develop in an infant in hours.
- Fever is a common reason why parents or caregivers call 9-1-1. A body temperature of 100.4°F (38°C) or higher is considered to be abnormal.
- Manage hypoglycemia in a pediatric patient in the same way you would in an adult, treating the symptomatic child with glucose if the blood glucose level is less than 80 mg/dL. Use pediatric IV glucose dosages based on the patient's age.
- Trauma is the number-one killer of children in the United States.
- Note and report any signs of abuse or neglect when assessing a pediatric patient, such as bruises in different stages of healing, burn patterns, fractures, developmental delay, or emotional indicators (withdrawn, afraid, hostile).
- If you suspect sexual abuse, limit your assessment to determining the type of dressing any injuries require. Do not allow the child to wash, urinate, or defecate before a physician completes an examination.
- A victim of SIDS will be pale or blue, not breathing, and unresponsive. The infant may show signs of postmortem changes, including rigor mortis and dependent lividity; if so, call medical control to report the situation.
- Carefully inspect the environment where a SIDS victim was found, looking for signs of illness, abusive family interactions, and objects in the child's crib.
- Provide support for the family in whatever way you can, but do not make judgmental statements.
- Any death of a child is stressful for family members and for health care providers. In dealing with the family, acknowledge their feelings, keep any instructions short and simple, use the child's name, and maintain eye contact.
- Be prepared to respond to philosophical as well as medical questions, in most cases by indicating concern and understanding; do not be specific about the cause of death.
- Be alert for signs of posttraumatic stress in yourself and others after dealing with the death of a child. It can help to talk about the event and your feelings with your EMS colleagues.

Vital Vocabulary

acrocyanosis A decrease in the amount of oxygen delivered to the extremities. The hands and feet turn blue because of narrowing (constriction) of small arterioles (tiny arteries) toward the end of the arms and legs; can occur at any age; may be benign in infants younger than 2 months.

adolescent A young person age 12 to 18 years.

apical pulse Obtained by auscultating heart tones over the chest with a stethoscope.

blanching Turning white.

blow-by oxygen A method of delivering oxygen by holding a face mask or similar device near the infant or child's face; used when a nonrebreathing mask is not tolerated.

bradycardia A slow heart rate; less than 60 beats/min in adults; less than 80 beats/min in children; and less than 100 beats/min in infants.

bradypnea Slow respiratory rate; ominous sign in a child; indicates impending respiratory arrest.

brief resolved unexplained event (BRUE) An event that causes unresponsiveness, cyanosis, and apnea in an infant, who then resumes breathing with stimulation.

capillary refill time The amount of time that it takes for blood to return to the capillary bed after applying pressure to the skin or nail bed; indicates the status of end-organ perfusion; reliable in children younger than 6 years.

central pulses Pulses that are closest to the core (central) part of the body where the vital organs are located.

child abuse Any improper or excessive action that injures or otherwise harms a child or infant; includes physical abuse, sexual abuse, neglect, and emotional abuse.

croup An infectious disease of the upper respiratory system, usually caused by a virus, that may cause partial airway obstruction and is characterized by a barking cough; usually seen in children; also referred to as laryngotracheobronchitis.

end-organ perfusion The status of perfusion to the vital organs of the body; determined by assessing capillary refill time.

epiglottitis An acute bacterial infection that results in rapid swelling of the epiglottis and surrounding tissues; may cause upper airway obstruction; also referred to as acute supraglottic laryngitis.

epiphyseal plate The growth plate of the bone; responsible for normal bone growth and development during childhood.

febrile seizures Seizures that result from sudden high fever, particularly in children.

fontanelles Areas where the neonate's or infant's skull bones have not fused together; usually disappear at approximately 18 months of age.

functional residual capacity The volume of air remaining in the lungs following exhalation; also referred to as oxygen reserve.

generalized tonic-clonic seizures Seizures characterized by severe twitching of all of the body's muscles that may last several minutes or more; formerly known as a grand mal seizure.

greenstick fracture An incomplete fracture of a bone; seen in children, whose bones are pliable and may not completely fracture.

grunting An "uh" sound heard during exhalation; reflects the child's attempt to keep the alveoli open; a sign of increased work of breathing.

infancy The first year of life.

intraosseous (IO) infusion Method of delivering fluids or medications into the medullary canal of the bone; used when intravenous access cannot be quickly obtained.

Jamshidi needle A double needle, consisting of a solid-bore needle inside a sharpened hollow needle; used to access the medullary canal for intraosseous infusion.

length-based resuscitation tape A tape used to estimate an infant or child's weight on the basis

of length; appropriate drug doses and equipment sizes are listed on the tape; one type is called a Broselow tape.

mediastinum The space between the lungs, in the center of the chest, that contains the heart, trachea, large blood vessels, main stem bronchi, part of the esophagus, lymphatic channels, and paired vagus and phrenic nerves.

medullary canal The space within the bone that contains bone marrow.

meningitis An inflammation of the meningeal coverings of the brain and spinal cord; it is usually caused by a virus or a bacterium.

nares The external openings of the nostrils.

neglect Refusal or failure on the part of the caregiver to provide life necessities, such as needed care, services, or supervision.

Neisseria meningitidis A form of bacterial meningitis characterized by rapid onset of symptoms, often leading to shock and death.

nuchal rigidity A stiff or painful neck; commonly associated with meningitis.

occiput The posterior (back) aspect of the head.

osteomyelitis Inflammation of the bone and muscle caused by infection; a potential complication of intraosseous infusion.

parenchyma The tissue of an organ itself.

pediatric assessment triangle (PAT) A structured assessment tool that allows you to rapidly form a general impression of the infant or child without touching the child; consists of assessing appearance, work of breathing, and circulation to the skin.

pertussis An airborne bacterial infection that affects primarily children younger than 6 years; patients will be feverish and exhibit a “whoop” sound on inspiration after a coughing attack; highly contagious through droplet infection; also called whooping cough.

preschool-age Between 3 and 6 years of age.

respiratory arrest The absence of respirations with detectable cardiac activity.

respiratory distress A clinical state characterized by increased respiratory rate, effort, and/or work of breathing.

respiratory failure A clinical state of inadequate oxygenation, ventilation, or both.

school age A child age 6 to 12 years.

septum A central divider, such as the nasal septum.

shaken baby syndrome Bleeding within the head and damage to the cervical spine as a result of intentional, forceful shaking of an infant or small child.

sniffing position An upright position in which the patient’s head and chin are thrust slightly forward to keep the airway open; the optimum head position for the uninjured child who requires airway management.

sudden infant death syndrome (SIDS) Unexpected death of an infant or young child that remains unexplained after a complete autopsy.

tachypnea Rapid respiratory rate.

tenting A sign of dehydration in which the skin slowly retracts after being pinched and pulled away slightly from the body.

tidal volume The amount of air (in milliliters) that is moved into or out of the lungs during one relaxed breath; approximately 500 mL for an adult.

toddler A child between 1 and 3 years of age.

tracheal tugging Pulling of the trachea into the neck during inspiration; a sign of increased work of breathing.

tragus The small cartilaginous projection in front of the opening of the ear.

vasoconstriction Narrowing of the diameter of a blood vessel.

Volutrol A special type of microdrip set; allows you to fill a large drip chamber with a specific amount of fluid to avoid fluid overload.

work of breathing An indicator of oxygenation and ventilation. Work of breathing reflects the child’s attempt to compensate for hypoxia.

Chapter 37

Geriatric Emergencies

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Special Patient Populations

Applies a fundamental knowledge of growth, development, aging, and assessment findings to provide basic and selected advanced emergency care and transportation for a patient with special needs.

Geriatrics

- Impact of age-related changes on assessment and care (pp 1799–1810)
- Changes associated with aging, psychosocial aspects of aging, and age-related assessment and treatment modifications for the major or common geriatric diseases and/or emergencies
 - Cardiovascular diseases (pp 1801–1802)
 - Respiratory diseases (pp 1800–1801)

Trauma

Applies fundamental knowledge to provide basic and selected advanced emergency care and transportation based on assessment findings for an acutely injured patient.

Special Considerations in Trauma

Recognition and management of trauma in the

- Geriatric patient (pp 1832–1833)

Pathophysiology, assessment, and management of trauma in the

- Geriatric patient (pp 1833–1835)

KNOWLEDGE OBJECTIVES

1. Define the term geriatrics. (p 1794)
2. Discuss the economic impact of aging, independent and dependent living, advance directives, and end-of-life care. (pp 1795–1797)
3. Discuss generational considerations when communicating with geriatric patients and their families. (pp 1797–1798)
4. Discuss how to respond to nursing or skilled care facilities. (pp 1798–1799)
5. Explain the leading causes of death among geriatric patients. (p 1799)
6. Discuss the normal physiologic changes that occur in various body systems as people age. (pp 1799–1810)
7. Describe the pathophysiology of common conditions affecting geriatric patients. (pp 1799–1810)
8. Discuss psychiatric emergencies in the older population. (pp 1803–1806)
9. Define polypharmacy, and explain the toxicity issues that can result. (p 1811)
10. Know the potential implications of a patient taking multiple medications. (p 1811)
11. Discuss special considerations when performing the patient assessment process on a geriatric patient with a medical condition. (pp 1811–1818)
12. Explain the GEMS diamond (Geriatric patients, Environmental assessment, Medical assessment, and Social assessment) and its role in the assessment and care of the geriatric patient. (pp 1813–1814)
13. Discuss emergency medical care of a geriatric patient including fluid resuscitation. (pp 1818–1819)
14. Discuss assessment and management of common conditions and injuries affecting geriatric patients, including respiratory, cardiovascular, neurologic, endocrine, gastrointestinal, renal, and toxicologic emergencies. (pp 1819–1832)
15. Explain special considerations for a geriatric patient who has experienced trauma, including performing the patient assessment process on a geriatric patient with a traumatic injury. (pp 1832–1838)
16. Discuss elder abuse and neglect, and its implications in assessment and management of the patient. (pp 1838–1840)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

Geriatrics is the assessment and treatment of disease and/or injury in someone 65 years or older. Prevention and management of disease and disability in later life are becoming more important as a result of an aging society (**FIGURE 37-1**). For some time, emergency medical services (EMS) education approached the treatment of geriatric patients with the same considerations as those for younger adults. Now this has changed.

A decline in our body systems starts in our late 20s and progresses slowly throughout our life span. Think of yourself and subtle changes you have seen as a result of aging. Perhaps you have noticed a slight deficit in eyesight or hearing, or difficulty in doing activities you had no problem doing 10 years ago. The reality is that we all age, and older persons

FIGURE 37-1 Working with geriatric patients is a large part of being an EMS provider.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

will continue to become a larger percentage of the population.

According to the US Census Bureau, the number of Americans aged 65 years and older has been increasing rapidly in the past decade, owing largely to the aging Baby Boomer generation. The total population of this demographic now stands at approximately 50 million people.¹ Calls involving geriatric patients may be challenging because the classic presentation of medical conditions common in younger patients may not be seen in older patients. For example, an acute myocardial infarction (MI) may present in an atypical fashion in an older patient; nonspecific symptoms such as weakness, dizziness, or nausea are not uncommon. Some older patients may not experience chest pain or pressure (ie, a silent MI). An aging body can mask serious medical conditions. Older patients frequently have chronic medical problems and may be taking numerous medications for their illnesses. Providing effective treatment for this increasing number of patients will require you to understand the issues related to aging and modify some of your assessment and treatment approaches.

We should respect the wealth of knowledge that older patients have to offer. In many countries, older people are treated with reverence. In many other cultures, older people are seen as a valuable resource of history. In Japan, there is a “Respect for the Aged Day.” This same degree of respect may not be shared by many people in the United States, but as an advanced emergency medical technician (AEMT), you must remember to treat every patient the way you would want your loved ones to be treated.

General Considerations

The Economic Impact of Aging

As an AEMT, you need to be aware of the economic impact of aging. Many older people today did not have the benefit of retirement planning. The Social Security Administration reports that the four major sources of income for older people are Social Security, income from assets, pensions, and earnings.² For most older people, Social Security is the major source of income.³ For many older people, this is their *only* source of income, forcing them to prioritize their needs on a monthly basis. Older people may not seek medical assistance because of the concern over cost.

The cost of prescriptions for older persons may cause some patients to either skip days of their medication or cut their dosage in half. More than one-fifth of adults report not taking their medicines as prescribed due to the expense.⁴ Therefore, many older people who have reached retirement age continue to be a part of the workforce to supplement their limited income.

Words of Wisdom

Some patients, to save money, may inadvisably decide to halve their medications, thus turning a 30-day supply of medications into a 60-day supply. Stress the importance of taking medications in the strength prescribed. Take the time to familiarize yourself with programs that may help to pay for medications for those who cannot afford them.

YOU are the Provider

Part 1

Your ambulance is dispatched to a local apartment complex for an unknown medical problem. On your arrival, you are greeted at the door by a distraught middle-aged woman who states she came over to check on her elderly father, and he was not acting normally. As you approach the patient, he informs you that his name is Darwin Feakes and that he is 82 years old, but he appears slightly confused about anything else. His daughter tells you that he has been getting progressively “senile” over several years, has numerous medical problems, takes numerous medications, and that he has lived by himself since her mother died last year.

1. What are some possible causes of confusion in geriatric patients?
2. Does this patient present with any risk factors that could affect his mortality?

Independent and Dependent Living

Not all geriatric patients you are called to assist will be living in a nursing home. Many older patients are able to live independently. You may also encounter senior citizens who are the primary caregiver for their parent or parents. Often, these patients will be living in the same home in which they grew up. Be aware that many of these patients have a fear that if you take them to the hospital, they will never see their home again.

Most healthy older adults strive to live independently. They may believe that they are able to care for themselves and handle **activities of daily living (ADLs)** such as tooth brushing, showering, and dressing. When one of the adults becomes ill and can no longer handle the ADLs, that person becomes dependent on others in the home. Someone else in the home may become a caregiver. Many older couples or friends and family who live together can provide basic assistance for each other; however, some older patients do not have family or friends to assist them. They are totally dependent on themselves, may attempt to do everything on their own, and may not seek available assistance. Patients who become isolated from outside social events are susceptible to self-abuse or alcohol or medication abuse.

When older adults cannot care for themselves, their family may decide to care for them in the home, possibly with the assistance of a visiting nurse agency. Outsiders, as well as the AEMT, may believe the patient can receive better care in a dependent care facility. You need to remember that families have their reasons for wanting an older patient to stay in a familiar home environment. Sometimes older patients refuse to accept that they need assistance and may not be aware of the danger in insisting on caring for themselves. The care of an older patient may fall on a spouse or family members who may have additional medical problems themselves. You may respond to a home or facility for a patient only to find out that the caregiver is more in need of care than the patient. The stress of caring for a chronically ill person can become overwhelming. Caregivers may neglect their own health care and/or social needs. Caregivers may be afraid to leave the house, may limit social interactions, and may need help coping with stress.

Dependent living (sometimes known as residential care) has many different levels of assistance. The level is based on two factors. One level of care is based on the needs of the person, while the other level of care is based on restrictions that are placed on the person. Dependent care can range from the least restrictive retirement community to the structured skilled nursing facility to specialty care facilities for patients with dementia or Alzheimer disease.

Advance Directives and End-of-Life Care

Mentally competent adults and emancipated minors have the right to consent to or decline treatment. To prepare for the possibility that they become mentally incompetent, many people today are making use of advance directives. Advance directives are legal documents that specify the desired medical treatment for a competent patient, should the person become unable to make decisions.

Advance directives may take the form of do-not-resuscitate (DNR) orders, sometimes called do-not-attempt-resuscitation (DNAR) orders. DNR orders give you permission not to attempt resuscitation for a patient in cardiac arrest. Even in the presence of a DNR order, you are still obligated to provide supportive measures that may include oxygen delivery, pain relief, and comfort when you can. DNR does not mean do not treat. Learn and become familiar with your state laws regarding this issue.

You may also encounter an end-of-life document known as Physician Orders for Life-Sustaining Treatment (POLST). Although similar to a DNR, the POLST is more expansive and encourages physicians to speak with patients with a terminal illness and create specific orders to be followed at the end of life. A DNR generally applies to patients who are in cardiac arrest, whereas POLST may apply to patients with such conditions as impending pulmonary failure who are not in cardiac arrest.

In the absence of an advance directive or DNR, some patients may have a durable power of attorney for health care or a health care proxy, a named surrogate to make decisions for them regarding their health care in the event they are incapacitated and unable to make decisions themselves. Be sure to follow your service's protocol when faced with any advance directive. For more information about

consent, advance directives, and durable powers of attorney for health care, see Chapter 3, *Medical, Legal, and Ethical Issues*.

You will inevitably be involved with end-of-life care for patients. Many communities have nursing home facilities (residential facilities with health care), **hospice** services (care provided for the terminally ill, whether inpatient or outpatient), and home health care programs (patients are treated in their homes). If these programs exist in your community, consider how you or your service might collaborate on providing quality care for a person at the end of life.

Street Smarts

There is much you can do to assist with end-of-life care, beginning with demonstrating a caring and concerned attitude and approach.

Communicating With Older Patients and Spouses

Communication is the key to a productive encounter with a patient. Consider your own personal communication skills. Does the patient understand what you are saying, asking, or doing? When the patient is sitting in a chair, bend down or position yourself at the patient's level to speak directly to the patient, allowing the patient to see your face. Maintaining eye contact and speaking in a steady tone will assist you in communicating with the patient. You may be required to repeat a question or statement when it appears that the patient does not comprehend what you are asking or saying. Ask as many open-ended questions as possible and use closed-ended questions to clarify points.

Avoid being overly familiar with the patient, and do not use first names or nicknames unless the patient asks you to. Avoid being judgmental. You must be able to gain your patient's confidence, which is best accomplished by treating the patient with respect; taking a slow, deliberate approach; and explaining what you are doing. Be sure to have one provider obtain the patient's history, one question at a time, providing as much privacy as possible (**FIGURE 37-2**). After interviewing the patient, ask family members or caregivers to clarify what

FIGURE 37-2 A slow, deliberate approach to the patient history, with one AEMT asking the questions, is generally the best strategy in assessing an older patient.

© John Moore/Getty Images News/Getty Images.

you just learned from the patient. Past medical conditions can provide information about the patient's current problem. Older patients often have more than one chronic condition, and the symptoms of one disease may make the assessment of another more difficult. Do not assume that just because a patient is older, the person is unable to communicate, and do not assume an altered mental status is *normal*.

An AEMT may encounter a geriatric couple who has been together for many years with no other immediate family. In times of crisis, the patient is cared for, and the spouse may be forgotten. If the spouse cannot drive, there may be no way for the person to get to the hospital. Depending on circumstances, it may also be difficult for the spouse to contact the hospital or follow up on the loved one's progress. You can help by simply asking a bystander, firefighter, police officer, or anyone who is not directly caring for the patient to help the spouse into

Street Smarts

When communicating with an older patient, choose appropriate terminology or describe conditions to eliminate confusion. For example, when asked about patient history, an older patient may say, "I have sugar and high blood." These terms are often used in place of diabetes and hypertension, respectively, if the patient is not familiar with the appropriate terminology.

the passenger seat of the ambulance and to fasten the seat belt so that when you are ready to go, the spouse is ready also.

For more information about communicating with older patients, see Chapter 4, *Communications and Documentation*.

Response to Nursing and Skilled Care Facilities

Nursing homes or skilled care facilities are common locations in which the AEMT will encounter an older patient. Before you provide transport for the patient, you should find out the following critical information from the nursing staff:

- What is the patient's chief complaint today?
- What is the patient's admitting diagnosis? In other words, what is the initial problem that led to admission to the facility?

To determine the nature of the problem, you will usually have to compare patients' present condition with their condition before the onset of the symptoms. Ask the staff about the patient's mobility, ADLs, and ability to speak. This will help to establish the patient's baseline condition and determine whether today's behavior differs.

Many facilities that are transferring patients will include a transfer record containing the patient's medical history, medication lists and dosages, previous diagnoses, vital signs, allergies, and additional information. These records provide you, as well as other health care providers who will be involved in the care of the patient, with essential information and will save time, especially when the patient cannot provide this information. Be sure to obtain this essential record before leaving for the hospital and relay it to the hospital staff when giving your report.

Infection control needs to be a high priority for AEMTs when visiting these facilities. You not only need to protect yourself, but you also need to inhibit the spread of pathogens from patient to patient. Good handwashing and standard precautions can inhibit the spread of infectious pathogens to people who already have compromised immune systems. An infection in an older patient can lead to life-threatening sepsis. Infections such as **methicillin-resistant *Staphylococcus aureus* (MRSA)** are common among people who

are living in close quarters such as nursing homes. The organism can be found in decubitus ulcers (bed sores), on feeding tubes, and on indwelling urinary catheters. The symptoms of MRSA depend on the type of infection. The bacteria can cause mild infections on the skin or invade the bloodstream, lungs, or the urinary tract. MRSA is primarily spread by broken skin-to-skin contact but is also acquired by touching objects that have the bacteria on them.

Safety

Due to the confining nature and patient population, nursing homes pose a high risk for spreading respiratory illnesses such as coronavirus disease 2019 (COVID-19). Residents often include older adults and those with chronic medical conditions that make them more susceptible to the pathogens that cause COVID-19. Strict adherence to infection control policies, including wearing masks, gloves, and eye protection and frequently washing the hands, are essential to preventing disease spread in enclosed spaces.

Similarly, many infections in hospitals are caused by vancomycin-resistant enterococci. Enterococci are bacteria that are normally present in the human intestines and the female genital tract. Under the right circumstances, these bacteria can cause infection. Some of the enterococci have become resistant to the antibiotic commonly used to treat these infections, which is vancomycin.

The **respiratory syncytial virus (RSV)** causes an infection of the upper and lower respiratory tracts. Although more typically seen in children, the virus can also cause serious illness in geriatric persons, especially in those with lung disease or weakened immune systems. The symptoms are similar to those of the common cold but can be more severe and last longer. The virus is highly contagious and is found in discharges from the nose and throat of an infected person. RSV is also transmitted by direct contact with droplets from coughs or sneezes and by touching a contaminated surface.

MRSA and RSV infections can be life threatening, especially in an immunocompromised patient. Look for "isolation" signs or ask about contagious disease when you approach a patient. Be sure to

wear appropriate personal protective equipment and decontaminate your ambulance and diagnostic equipment after contact with nursing home residents if there is a history of infectious disease or if the patient shows signs and symptoms of a potentially infectious disease. Be sure to document the infection control issue; advise the receiving facility; and, depending on local protocol, report any infectious disease to your company or the local health department.

Clostridioides difficile is a bacterium responsible for the most common cause of hospital-acquired infectious diarrhea and regularly causes sporadic cases of diarrhea in nursing homes. The bacterium normally grows in the intestines. Antibiotic use may account for the rapid increase in toxic strains that ultimately cause illness. Health care workers may carry this bacterium following contact with contaminated feces. It can also be found on environmental surfaces like furniture, floors, toilets, sinks, and bedding. The symptoms from the resultant colitis can range from minor diarrhea to a life-threatening inflammation of the colon.

You should also be cognizant of potential airborne pathogens. Something as simple as a cold or flu virus could result in a life-threatening pneumonia for a compromised older adult. Be sure to wear a mask if you have an upper respiratory infection, and mask patients if they have one.

Leading Causes of Death

The leading cause of death in older people is heart disease, followed by cancer, chronic lower respiratory disease, stroke, Alzheimer disease, diabetes, trauma, and pneumonia.⁵ Contrary to popular belief, people do not die of “old age.” The aging physiology of older people makes them more vulnerable than younger people to the effects of disease and injury. In addition, acute illness and trauma are more likely to involve organ systems beyond those initially involved. For example, an older person who has fallen and fractured a hip may develop pneumonia during recovery resulting from immobility and aspiration. Other associated risk factors that affect mortality in older patients include the following:

- Living alone
- Recent death of a spouse or significant other
- Immobility
- An altered mental status.

Anatomy, Physiology, and Pathophysiology

As people get older, their anatomy and physiology change. In general, 65-year-old people cannot expect to have the same degree of physical performance as when they were 30 years old. Organ systems begin to deteriorate, the heart muscle thickens, the arteries become less elastic, valves degenerate, and maximum vital capacity of the lungs may decline. However, the aging process does not necessarily mean that a person will experience disease. Some geriatric patients remain in excellent health throughout their lives and may not have the comorbidities seen in their counterparts.

Common stereotypes about older persons include the presence of mental confusion, illness, a sedentary lifestyle, and immobility. Although these perceptions are common, they are usually far from the truth. Older persons can continue to stay fit and active even though they will not be able to perform at the same level as they did in their youth (**FIGURE 37-3**). Most older people lead very active lives, participating in sports and in the community, and they are generally healthy despite the aging process. As body systems age, they undergo several important changes, for example:

- Motor nerves begin to deteriorate; ability to react quickly decreases.
- Blood pressure steadily increases.
- Ability to maintain normal body temperature decreases.

FIGURE 37-3 Older people can continue to stay fit and active.

Courtesy of the National Cancer Institute.

- Muscles become less flexible and strength declines.
- Oxygen/carbon dioxide exchange in the lungs and at the cellular level declines, and the body fatigues at a faster rate than when younger.
- Metabolism rate decreases; weight gain may result.

Changes in other body systems are outlined in the following sections.

Changes in the Respiratory System

A person's respiratory capacity undergoes substantial reductions with age for several reasons. As a person ages, the alveoli become enlarged, but their elasticity decreases, making it harder to expel the used air in an older person's lung tissue. This lack of elasticity, caused by a decrease in pulmonary surfactant, results in a decreased ability to exchange oxygen and carbon dioxide, which further causes an increase in residual volume (the amount of air left in the lungs at the end of a maximal exhalation). The body's receptors that monitor the changes in oxygen and carbon dioxide slow with age, which causes lower pulse oximetry (SpO_2) readings even in healthy people. Thus, although the total amount of air in the lungs does not change with age, the proportion of that air used in gas exchange progressively declines. Airflow, which depends largely on airway size and resistance, also deteriorates somewhat with age.

Meanwhile, changes in the distribution of blood flow within the lungs result in a declining partial pressure of oxygen in arterial blood (PaO_2). As the aging process takes place, a decline in PaO_2 can have a substantial effect on the patient's ability to maintain homeostasis. Furthermore, the respiratory drive becomes dulled as a person ages because of decreased sensitivity to changes in arterial blood gases or decreased central nervous system (CNS) response to such changes. Consequently, older people have a slower reaction to hypoxemia and hypercapnia.

Another important change is that calcification tends to make the chest wall stiffer. Other musculoskeletal changes, such as **kyphosis** (outward curvature of the thoracic spine; also called hunchback), may also affect pulmonary function by limiting lung volume and maximal inspiratory pressure. In addition, the lung's defense mechanisms become

less effective as a natural consequence of aging. The cough and gag reflexes decrease with age, increasing the risk of aspiration. Furthermore, the ciliary mechanisms that normally help remove bronchial secretions are markedly slowed. A decrease in the number of cilia that line the bronchial tree lessens the ability to cough and therefore increases the chances of infections such as pneumonia.

Finally, with aging, decreases occur in the size and strength of the respiratory muscles. Therefore, a patient who is having trouble breathing may not be able to compensate as well with accessory muscles as a younger person would. This means there is an increased likelihood of an airway obstruction from either secretions or food particles.

Although tobacco abuse seems to be decreasing among older patients, chronic lower respiratory disease and pneumonia remain in the top causes of geriatric deaths.⁵ In fact, one of the most common causes of death in older patients is infection with *Pneumococcus* bacteria.

Pneumonia is an infection of the lungs that may be bacterial, fungal, or viral in origin. Those most at risk include anyone who already has a preexisting chronic disease of the lungs, those in institutions such as nursing homes, patients with chronic obstructive pulmonary disease (COPD) and cancer, immunocompromised patients, and those who have inhaled toxins or aspirated.

Street Smarts

Placing a mask on a patient with a respiratory infection such as pneumonia, tuberculosis, or COVID-19 helps stop the transmission of the pathogen, but it can also increase the patient's difficulty breathing and produce anxiety. Consider placing the mask over the nonbreathing mask.

Another condition that can cause respiratory distress in older people is a **pulmonary embolism**. Pulmonary embolism is a condition that causes a sudden blockage of an artery by a venous clot. Clots develop in the veins of the legs or pelvis and then break off and embolize (move) through the pulmonary artery or one of its branches, where they lodge. This potentially life-threatening condition can present as another disease. A patient with a pulmonary embolism will generally complain of symptoms of

chest pain; thus, the pulmonary embolism can be confused with a cardiac, lung, or musculoskeletal problem. Risk factors for a pulmonary embolism include recent surgery (especially in a lower extremity), history of blood clots or first-degree relative with history of blood clot, obesity, cancer, recent long-distance travel, and sedentary behavior, especially after surgery. Other conditions that render the patient bedridden also increase the risk of a pulmonary embolism.

Changes in the Cardiovascular System

A variety of changes occur in the cardiovascular system as a person grows older that decrease the efficiency of the system. Specifically, the heart hypertrophies (enlarges) with age, probably in response to the chronically increased afterload imposed by stiffened blood vessels. Bigger is not better, however. Over time, cardiac output declines, mostly as a result of a decreasing stroke volume. (Cardiac output, which is the amount of blood pumped from the heart in 1 minute, is a measure of the workload of the heart.) Normally, an increased demand on the cardiovascular system is compensated for by increasing the heart rate, increasing the contraction of the heart, and constricting the blood vessels to nonvital organs to shunt blood to vital organs. However, aging decreases a person's ability to increase the heart rate, increase cardiac contraction strength, and constrict blood vessels (called **vasoconstriction**) because the vessels are stiffer.

Also, over time, it is normal that the electrical conduction system will show signs of wear. The cells of the sinoatrial node (the heart's primary pacemaker) will decrease in number and in function;⁶ therefore, dysrhythmias may begin to develop.

Some changes in cardiovascular performance are probably not a direct consequence of aging, but rather reflect the deconditioning effect of a sedentary lifestyle. Whether because of other disabilities (such as arthritis) or for psychological reasons, many people tend to limit physical activity as they grow older. The bodybuilder's slogan, "Use it or lose it," applies just as much to the cardiac muscle as to the biceps.

Many older patients are at risk for **atherosclerosis**, an accumulation of fatty material in the arteries (**FIGURE 37-4**). Major complications

FIGURE 37-4 Atherosclerosis, the buildup of fatty plaque on arterial walls, may progress to the point that the plaque occludes the artery.

© Jones & Bartlett Learning.

of atherosclerosis include MI and stroke. The presence of **arteriosclerosis**, a disease that causes the arteries to thicken, harden, and calcify, increases the risk of stroke, heart disease, hypertension, and bowel infarction.

Older people are also at an increased risk for an **aneurysm**, a weakening in the wall of a blood vessel (usually an artery), resulting in an area of dilation or "ballooning" of the vessel. Severe blood loss occurs when an aneurysm ruptures.

Abdominal aortic aneurysm (AAA) is one of the most rapidly fatal conditions. In 2018, 9,923 deaths were primarily caused by AAA.⁷ Major risk factors for AAA include age greater than 60 years, male sex, smoking, hypertension, and a family history of AAA.

With an AAA, the walls of the aorta weaken and blood begins to leak into the layers of the vessel, causing the aorta to bulge like a bubble on a tire. If enough blood is lost into the vessel wall itself, shock occurs. If the wall bursts, it rapidly leads to fatal blood loss. If the aneurysm is detected early, there is a chance to repair the vessel before rupture and fatal blood loss occur.

A patient with an AAA most commonly reports abdominal pain radiating through to the back with occasional flank pain. If the AAA becomes large enough, it can be felt as a pulsating mass just above and slightly to the left of the umbilicus during your physical examination. Occasionally, the AAA causes a decrease in blood flow to one of the legs,

and the patient complains of some discomfort in the affected extremity. Assessment may also reveal diminished or absent pulses in the extremity. Evidence of shock as a result of blood loss is common. Because of a decrease in blood volume and decreased blood flow to the brain, the patient may experience **syncope** (fainting).

Changes in the Nervous System

Aging produces changes in the nervous system that are reflected in the neurologic examination. By age 80 years, a 10% to 20% reduction in brain weight can result in increased risk of head trauma owing to a larger area in the skull in which the brain can move during injury.⁸ The human brain has an enormous reserve capacity, and having a smaller, lighter brain does not generally interfere with the mental capabilities of productive older people.

Short-term memory impairment, a decrease in the ability to perform psychomotor skills, and slower reflex times are all normal in the aging process. Because of deterioration of the nervous system and its control over various functions, you may see changes in the rate and depth of respirations, heart rate, blood pressure, hunger, thirst, and temperature. This decline may make assessment of the older patient challenging. Because of these changes, your patient may have slower responses to questioning or may request that you repeat a question. It is vital to establish a baseline mental status when assessing a patient with an altered mental status. Never assume it is a normal part of aging.

Undeniably, the performance of most sense organs declines with increasing age. Hearing begins to decline around 40 years of age. At 50 years of age, vision and tactile senses decrease. Taste senses begin to change around 60 years of age, although the ability to smell does not begin to diminish until 70 years of age. Sense of body position (**proprioception**) also becomes impaired with age. Proprioception enables us to maintain postural stability by using a variety of receptors in the joints and information provided by the eyes. As these mechanisms fail with age, people become less steady on their feet, and the tendency to fall increases markedly.

Vision

As people age, the pupils begin to lose the ability to handle changes in light and require more time to

adjust. Decreases in visual acuity are common in older people, possibly in association with diseases such as central retinal vein occlusion and central retinal artery occlusion, but they can occur even without disease processes. Aging affects an older person's ability to differentiate color, and tear production also decreases. Light changes and the increase in glare can cause problems of visual acuity and depth perception. Night vision becomes impaired. These changes can make driving and walking more hazardous, which can increase the risk of falls and affect an older person's independence.

The two most common causes of visual disturbances in older people are cataracts and glaucoma. A **cataract**, clouding of the lenses or their surrounding membranes, may interfere with vision and make it difficult for an older patient to distinguish colors and see clearly, increasing the likelihood of falls, accidents, and mistakes in taking medications. Cataracts are a result of hardening of the lenses over time. The lenses eventually become opaque, which prevents light and images from being transmitted to the rear of the eye. Patients with cataracts may complain of blurred vision, double vision, spots, and/or ghost images. Surgical treatment may be required to gain vision. By contrast, **glaucoma** is caused by an increase in intraocular pressure severe enough to damage the optic nerve, potentially resulting in permanent loss of peripheral and central vision. Treatment of glaucoma consists of oral medications and eye drops.

Macular degeneration, a condition that is common in persons with diabetes, is a disease that causes vision loss in the central part of the visual field. The macula in the retina of the eye is responsible for detailed vision such as reading. This disease may cause small or large items to seem different than they really are. Color perception can also vary within both eyes. Patients with macular degeneration have the ability to see outlines of objects but the center portion of the object may appear as a dark spot.

Retinal detachment is another problem in older patients. This is a disorder in which the retina peels away from the underlying support tissue and can result in vision loss and blindness.

Hearing

Approximately 25% of patients between 65 and 74 years of age have a disabling hearing loss. It increases to nearly 50% in those who are 75 years and

Words of Wisdom

When you are treating a patient with a visual impairment, always stay in direct contact with the patient. Allow the patient to rest a hand on your arm or leg for comfort. Also explain any procedures in advance so that your patient is not taken by surprise.

older.⁹ Changes to the ear can also cause problems with balance, increasing the risk of falls.

Changes in the inner ear make hearing high-frequency sounds difficult; muffled sounds are sometimes not even heard. For this reason, increasing the volume of your voice may not make it any easier for the patient to hear your words. To compensate for the hearing deficits, many older patients are prescribed hearing-assistance devices (eg, hearing aids). Although these devices may not return hearing to normal levels, they can increase your ability to communicate with the patient, so consider assisting the patient to insert a hearing device. Many audiologists have brochures to help patients with these devices. It would be beneficial for you to read this same information and obtain additional training about inserting a hearing aid.

A common cause of hearing impairment in geriatric patients is **presbycusis**, a progressive hearing loss, particularly in the high frequencies, along with a lessened ability to discriminate between a particular sound and background noise. Patients who lose the ability to interpret speech experience a decreased ability to communicate, which may result in isolation and depression.

For many older people, physiologic changes make it difficult to produce speech that is loud enough, clear, and well-spaced. Weakness, paralysis, poor hearing, or brain damage can impair a person's ability to produce speech.

Words of Wisdom

Always position yourself so that you are on the "good" side of the patient with a hearing deficit. Because hearing deficits usually involve the loss of high-frequency sounds, yelling in the patient's ear will only serve to further distort the patient's hearing.

Taste

Changes in appetite may occur because taste buds decrease in number as a person ages. Remaining taste buds also begin to shrink.¹⁰ Although these changes are gradual, the salty and sweet sensation appears to be among the first to diminish. A patient with diminished taste may not be able to discern fresh food from spoiled food. Older people commonly add large amounts of salt to their food in an attempt to improve its taste, but doing so could be dangerous for a patient with a history of hypertension.

Touch

The sense of touch decreases from loss of specialized nerve fibers. This loss, in conjunction with the slowing of the peripheral nervous system, can result in a delayed reflex reaction when an older person touches something hot, causing a burn. Alterations in pain perception can result in patients not calling EMS when needed. A syncopal episode or tightness in the chest may not be viewed as a sign of an impending heart attack. Despite these changes, the touch of a provider's hand may be comforting and reassuring and should be considered in your assessment. Many older patients may grasp your hand as a means for comfort or during severe pain episodes.

Smell

The sense of smell is among the last to diminish in older patients. However, factors such as upper respiratory infections (ie, the common cold), to which older persons are more susceptible, can affect the sense of smell.

Disorders Affecting Mental Status

Delirium

Delirium is a change in mental status that is marked by the inability to focus, think logically, and maintain attention. Acute anxiety may be present in addition to the other symptoms. Usually, memory remains mostly intact. Delirium is commonly marked by an acute or recent onset (generally within minutes, hours, or days) and is a "red flag" (a serious, potentially life-threatening problem) for some type of new health problem. Signs and symptoms of delirium include disorganized thoughts, inattention, memory loss, disorientation, hallucinations,

delusions, or changes in level of consciousness. You may also see changes in pupillary response, motor tests, blood pressure, and breath sounds.

Delirium may be caused by tumors, fever, urinary tract infections (UTIs), bowel obstructions, dehydration, cardiovascular disease, hyperglycemia, hypoglycemia, nutritional deficiencies, psychiatric disorders such as depression, environmental emergencies, or drug, alcohol, or sedative intoxication or withdrawal. Delirium can be present from metabolic causes as well. Any time a patient has an acute onset of delirious behavior, you should rapidly assess the patient for the following four conditions:

- Hypoxia
- Hypovolemia
- Hypothermia
- Hypoglycemia

Any of these four conditions, if left unrecognized or untreated, may be rapidly fatal. Delirium is short in its onset and usually correctable if identified early.

Dementia

Dementia is the slow onset of progressive disorientation, shortened attention span, and loss of cognitive function. It is a chronic, generally irreversible condition that causes progressive loss of cognitive abilities, psychomotor skills, and social skills. Dementia develops slowly over a period of years rather than a few days. Causes include Alzheimer disease, genetic factors, various forms of encephalitis, a history of working with metals or organic or airborne toxins, and cerebrovascular accidents (strokes). The patient's history and determination of function in the recent past are key factors in determining the difference between delirium and dementia. A patient with dementia may be experiencing a delirious event. Delirium is caused by emergent problems; dementia is not.

Words of Wisdom

Dementia and delirium are different disorders, yet they both present with alterations in mental status. Dementia is a chronic problem (ie, Alzheimer disease), whereas delirium is an acute problem (ie, hypoglycemia). Because both delirium and dementia can present in a similar manner, it is important to determine the patient's baseline mental status.

Signs and symptoms of dementia take months to years to become apparent and may include short-term memory loss or shortened attention span, jargon aphasia (talking nonsense), hallucinations, confusion, disorientation, inability to perform ADLs, difficulty in learning and retaining new information, and personality changes such as social withdrawal or inappropriate behavior. Patients with dementia will often be angry and uncooperative. Dementia is not synonymous with delirium, however, and a patient with dementia can also have delirium.

Safety

Be alert when caring for any patient exhibiting an altered mental status, even if it is normal for that patient. Some patients with dementia, Alzheimer disease, or other illnesses can become extremely violent, posing a danger to family as well as rescuers.

Neurodegenerative Diseases

Alzheimer Disease

Alzheimer disease is believed to be caused by the death of neurons in the brain. The disease begins gradually, with a person having difficulty performing routine tasks and/or forgetting recent events. As the disease advances, personality changes, impaired judgment, and an impaired ability to communicate thoughts or ideas become more prominent. In 2020, approximately 5.8 million Americans were living with Alzheimer dementia; of those, 82% were 75 years or older.¹¹ Onset before 65 years of age is known as early-onset Alzheimer disease.

In Alzheimer disease, symptoms may present as confusion (lack of familiarity with surroundings), changes in personality or judgment, and extreme difficulty with daily activities, such as feeding, bathing, and bowel and bladder control.

Parkinson Disease

Parkinson disease involves the nerve cells in the motor area of the brain and is caused by the insufficient formation and action of dopamine, a neurotransmitter that carries messages. It is a chronic and progressive disorder that worsens over time. In 2020, almost 1 million Americans were living with Parkinson disease.¹²

Parkinson disease may present as dyskinesia (involuntary movements or tremors affecting one or both sides of the body), dementia, depression, autonomic dysfunction (bladder and gastrointestinal [GI] problems), and postural instability (loss of reflexes or inability to “right oneself”). The involuntary movements or tremors appear to increase during times of stress and normally can be seen when a patient is sitting still.

Depression and Suicide

Late life can be a time of fulfillment and satisfaction, but for some older adults, it is characterized by physical pain, psychological distress, doubts about the importance of life’s accomplishments, financial concerns, loss of loved ones, dissatisfaction with living conditions, and seemingly unbearable disability. When these factors lead to hopelessness about the possibility for positive change in their lives, depression and, unfortunately, even suicide are possible outcomes. You are often the first health care professional to have contact with older adults who are depressed.

Depression is not part of normal aging, but rather a medical disease. It is treatable with medication and therapy; however, if depression goes

unrecognized or untreated, it is associated with a high suicide rate in the geriatric population.¹³ Depression in older patients can mimic the effects of many other medical problems (such as dementia). Risk factors for depression in older people include a history of depression, chronic disease, and loss (function, independence, or significant others). Approximately 40% of older adults residing in skilled nursing facilities are affected.¹⁴ Depression may be difficult to recognize in older people because many do not want to complain about feeling sad, worthless, or unwanted.

Unlike a normal experience of sadness, grief, or loss, depression is extreme and persistent and can interfere substantially with an older adult’s ability to function. It is impossible to predict which older adults will have depression, but substance abuse, isolation, prescription medication use, and chronic medical conditions all may contribute to the onset of substantial depression.¹⁵ Treatment of severe depression in older adults usually consists of psychological counseling, medication, or a combination of both. For many older adults, simply reestablishing relationships with the community or with family is enough to lessen the severity of the illness.

Older adults may not pursue medical treatment for psychological issues. Many older adults do not

YOU are the Provider

Part 2

As you perform your physical exam on the patient, you note that he is cold to the touch, has delayed capillary refill, and has a thready radial pulse. The patient states that he has been vomiting up “foul” smelling emesis for the last 4 days, that he is weaker than usual, and that he gets extremely dizzy when he stands up. He asks to use the bathroom before transport and as you assist him to the standing position, you note that his radial pulse disappears and that he becomes extremely pale.

Recording Time: 1 Minute

Appearance	Pale, poor general impression
Level of consciousness	Alert and oriented to person, place, time, and event, but slow to respond
Airway	Patent
Breathing	Nonlabored
Circulation	Prior to taking orthostatic vital signs: thready, slow radial pulses; skin cool, pale, and clammy

- Does this patient require immediate transport?
- On the basis of the patient’s presentation, what do you suspect is happening?

seek care and also frequently deny the problem when asked about it. It is vital that all members of the health care team be aware of these issues and take appropriate steps to ensure patient safety and well-being.

Changes in the Musculoskeletal System

Aging is associated with a widespread decrease in bone mass in men and women, especially among postmenopausal women. Bones become more brittle and tend to break more easily. Narrowing of the intervertebral disks and compression fractures of the vertebrae contribute to a decrease in height as a person ages, along with changes in posture. Joints lose their flexibility naturally with age and may be further impaired by arthritic changes. A decrease in the amount of muscle mass often results in less strength.

Changes in physical abilities can affect older adults' confidence in their mobility. Muscle mass decreases throughout the body, with an accompanying decrease in muscle strength. Muscle fibers become smaller and fewer, motor neurons decline in number, and strength declines. The ligaments and cartilage of the joints lose their elasticity. Cartilage also goes through degenerative changes with aging, contributing to arthritis. From an AEMT's perspective, the changes in the musculoskeletal system most often translate into fractures incurred as the result of falls.

Posture also changes as flexion at the neck and an anterior curling of the spine produce a condition called kyphosis (also called humpback or hunchback) (**FIGURE 37-5**), making immobilization of older persons more challenging.

Osteoporosis, a condition that affects women to a greater extent than men, is characterized by a decrease in bone mass resulting in reduction in bone strength and greater susceptibility to fracture. The extent of bone loss that a person undergoes is influenced by numerous factors, including genetics, smoking, level of activity, diet, alcohol consumption, hormonal factors, and body weight. The most rapid loss of bone occurs in women during the years following menopause, and many perimenopausal women take bisphosphonates or use hormone replacement therapy to help reduce bone loss. Calcium and vitamin D supplementation

FIGURE 37-5 Kyphosis, which can occur with aging, is a condition in which the spine has excessive forward curvature. This may lead to the shoulders being positioned forward.

© Dr. P. Marazzi/Science Source.

is important for bone health, but to improve bone strength and treat osteoporosis, other medication is required. Older people should remain active and engage in a low-impact exercise program to maintain bone and muscle strength.

Osteoarthritis is a progressive disease of the joints that destroys cartilage, promotes the formation of bone spurs in joints, and results in joint stiffness. This type of arthritis is thought to result from “wear and tear” and, in some cases, from repetitive trauma to the joints. It affects a substantial portion of the population older than 65 years. Typically, osteoarthritis affects several joints of the body, most commonly those in the hands, knees, hips, and spine. Patients report pain and stiffness that gets worse with exertion. The end result is often substantial disability and disfigurement. Patients are typically treated with anti-inflammatory medications and physical therapy to improve the range of motion.

Changes in the GI System

The process of digestion begins in the mouth, which is also where aging-related changes in the digestive

system may first be noted. A decrease in the number of taste buds and changes in olfactory receptors may diminish an older person's senses of taste and smell, which may also interfere with the enjoyment of food. The consequent decrease in appetite may result in malnutrition. Other changes in the mouth include a reduction in the volume of saliva, with a resulting dryness of the mouth making it harder to chew and begin to digest foods. Dental loss is not a normal result of the aging process, but rather the result of disease of the teeth and gums; nevertheless, dental loss is widespread in the geriatric population and contributes to nutritional and digestive problems.

Like oral secretions, hydrochloric acid in the stomach decreases, further inhibiting digestion as a person ages, although enough acid is still present to produce ulcers under certain conditions. Changes in gastric motility also occur, which may result in slower gastric emptying, a factor of some importance when assessing the risk of aspiration.

Function of the small and large bowel changes little as a result of aging, although the incidence of certain diseases involving the bowel (such as diverticulosis) increases as a person grows older. Slowing of the movement of food through the digestive tract may also result in constipation.

In the liver, there are changes in hepatic enzyme systems, with some systems declining in activity and others increasing. Notably, the activity of the enzyme systems concerned with the detoxification of drugs and alcohol declines as a person ages.

A cause of abdominal pain and shock is GI bleeding, which can occur for a variety of reasons, ranging from infection to ruptured varices to regular use of nonsteroidal anti-inflammatory drugs (NSAIDs) or alcohol to cancer of the stomach or esophagus. GI bleeding is usually heralded by vomiting of blood or material that looks like coffee grounds, called **hematemesis**. Bleeding that travels through the lower digestive tract usually manifests as black or tarry stools, called **melena**, whereas red blood in the stool usually means a local source of bleeding, such as hemorrhoids. A patient with GI bleeding may experience weakness, dizziness, dyspepsia, or syncope. A patient may also present with hepatomegaly (enlarged liver), jaundice, and agitation. Bleeding into the GI system can be life threatening because of the potential for blood loss and shock.

Bowel obstructions occur frequently in the geriatric population. The GI tract slows with aging and the patient can experience problems having bowel movements. Straining while attempting to have a bowel movement can stimulate the vagus nerve, resulting in vasovagal syncope, in which the heart rate drops dramatically and the patient becomes dizzy or passes out. The patient's condition will usually be stable on your arrival, but transport is required to rule out other causes of the syncopal episode. Another reason for bowel obstruction in older patients is the use of narcotic analgesics, which also decrease GI function.

Geriatric patients are at risk for dehydration as a result of diarrhea. Drug-related diarrhea and associated nausea and vomiting usually occur after a new medication is initiated or after a change in dosage. Infectious agents such as viruses and bacteria can cause acute diarrhea, which, if it lasts less than 4 weeks, is considered an illness. Chronic diarrhea is defined as lasting longer than the 4-week period.

Geriatric patients are at risk for food poisoning, also known as bacterial gastroenteritis, due to an increased likelihood of improperly handling or storing food as well as a decreased ability to identify spoiled food. Existing medical conditions such as dementia and age-related changes such as a diminished sense of taste or smell can contribute to these risks. Symptoms of *Salmonella* poisoning usually begin within 12 to 72 hours of eating and may last 2 to 3 days. *S aureus* will have a more rapid onset, usually within 2 to 8 hours, and the symptoms are typically more severe.

In addition, patients with lactose intolerance, constipation, reaction to certain cancer medications and treatments, and bowel obstructions may present with nausea, vomiting, or diarrhea.

Changes in the Renal System

Age is associated with changes in the kidneys as well. The kidneys are responsible for maintaining the body's fluid and electrolyte balance and have important roles in maintaining the body's long-term acid-base balance and eliminating drugs from the body. As the body ages, the kidney loses functioning nephron units, which translates into a lesser ability to effectively filter wastes. Also, renal blood flow decreases by as much as 50% as a person ages.

Although the kidneys of an older person may be capable of addressing day-to-day demands, they may not be able to meet unusual challenges, such as those imposed by illness. Therefore, acute illness in older patients is often accompanied by derangements in fluid and electrolyte balance. Aging kidneys, for example, respond sluggishly to sodium deficiency. An older patient may lose a great deal of sodium before the kidneys halt urinary sodium excretion, a problem that is exacerbated by the markedly decreased thirst mechanism in older people. The net result may be a rapid development of severe dehydration.

Conversely, older patients are at considerable risk of overhydration if they are exposed to large sodium loads (such as from intravenous [IV] saline solutions or heavily salted foods). The aging kidney is less able to excrete a large sodium load because of its lower glomerular filtration rate, making the patient vulnerable to acute volume overload.

The same factors that reduce an older person's ability to handle sodium also affect the body's ability to handle potassium. Thus, older patients are susceptible to hyperkalemia, which can become serious, even lethal, if the patient becomes acidotic or if the potassium load is increased from any source.

Urinary incontinence (involuntary loss of urine) can have a substantial social and emotional effect, but relatively few people admit to the problem and even fewer seek treatment. Incontinence can result in skin irritation, skin breakdown, and UTIs. As people age, bladder capacity decreases. Therefore, an older person may find it difficult to postpone voiding or may have involuntary bladder contractions. Two major types of incontinence are distinguished: stress and urge. Stress incontinence occurs during activities such as coughing, laughing, sneezing, lifting, and exercise. Factors contributing to urge incontinence in older adults include obesity, history of prostate surgery or prostate conditions, nerve damage from conditions such as diabetes or stroke, urinary tract infections, and certain cancers, such as bladder or prostate. Episodes may be triggered by hot or cold fluids, running water, and even thinking about going to the bathroom. Treatment of incontinence consists of medications, physical therapy, and, possibly, surgery.

The opposite of incontinence is urinary retention or difficulty urinating. Patients may have difficulty voiding or absence of voiding as a result of

many medical causes. In men, enlargement of the prostate (benign prostatic hypertrophy) can place pressure on the urethra, making voiding difficult. Bladder and UTIs can also cause inflammation. In severe cases of urinary retention, patients may have acute or chronic renal failure.

Changes in the Endocrine System

Hormone levels and the production of hormones change as we age. Diabetes develops when the body cannot oxidize complex carbohydrates (sugars) as a result of impaired pancreatic activity—namely, impaired production of insulin by the beta cells. With diabetes, more glucose is present in the blood than the body can handle. Geriatric patients with diabetes are at increased risk for hypoglycemia for several reasons: medications, inadequate or irregular dietary intake, inability to recognize the warning signs because of cognitive problems, and/or blunted warning signs. Delirium may be the only indication of hypoglycemia in an older patient.

The most common risk factor for this disease is having more than one chronic disease, and many older people with diabetes also have hypertension, heart disease, and stroke. Symptoms of an elevated blood glucose level (that is, hyperglycemia) include fatigue, poor wound healing, blurred vision, and frequent infections. Other symptoms of diabetes include the three Ps: polyuria, polydipsia, and polyphagia. Prevention of type 2 diabetes is aimed at changes in lifestyle that include dietary restrictions, exercise, and controlling obesity.

Hyperosmolar hyperglycemic nonketotic syndrome (HHNS), formerly called hyperosmolar nonketotic coma (HONK), is a metabolic derangement that occurs principally in patients with type 2 diabetes;¹⁶⁻¹⁹ however, approximately 20% of patients with HHNS do not have a prior diagnosis of diabetes.²⁰ This condition is characterized by hyperglycemia, hyperosmolarity, and an absence of significant ketosis; it is similar to diabetic ketoacidosis (DKA) in type 1 diabetes.

Physical changes noted during the assessment of the HHNS patient are primarily a result of excessive dehydration and hyperglycemia. Glucose levels are greater than 600 mg/dL. Warm, flushed skin with poor skin turgor and pale, dry oral mucosa are common findings. The tongue may be furrowed as well. In extreme cases of dehydration, the patient

may present with tachycardia, hypotension, and signs of shock.

Thyroid abnormalities also increase with aging. Many older patients remain asymptomatic, and the disease is diagnosed only when a routine blood test reveals a thyroid problem. With adult hypothyroidism, for example, the signs and symptoms may match those seen with normal aging: cold intolerance, constipation, dry skin, weakness, and so on. For acute-onset hyperthyroidism, the presentation can be blunted; although tachycardia is generally present, older patients may experience less tremor, anxiety, or hyperactive reflexes than younger patients do. Atrial fibrillation is more likely to be induced by an overactive thyroid gland in a geriatric patient. A smaller percentage of older patients with hyperthyroidism present with symptoms opposite those expected: weakness, lethargy, and depression.

Changes in the Immune System

Because nearly every function of the immune system is affected by aging, older persons are more susceptible to infection and secondary complications than are younger people. Chronic conditions such as diabetes, dementia, malnutrition, and cardiovascular disease place older people at greater risk of serious infection.

Older persons manifest infections differently. Although fever is often present with minor illness in young people, fever in older persons usually indicates a serious infection. However, not all older adults with a serious infection have a fever, owing to the decreased ability of the aging immune system to initiate a fever.

Sepsis occurs when an infection develops in the patient (which may be caused by bacteria, viruses, or fungi) and microorganisms or their toxic products enter the bloodstream. Sepsis may affect a part of (local) or the entire (systemic) body. The degree of sepsis can vary, from such a common occurrence as a dental abscess to the more severe sepsis, which affects more than one of the body's organs or systems. Septic shock occurs when hypoperfusion occurs following severe systemic infection. The signs and symptoms of septic shock may be fever, respiratory distress, increased pulse rate, generalized weakness, and hypotension. Site-specific infections may allow other signs and symptoms to be present. A patient with a UTI may have a foul odor

associated with the urine and sometimes pain on urinating or cloudy urine. Pneumonia is the leading cause of death from infection in Americans older than 65 years.⁵ Patients may develop infections through their lungs, through a urinary catheter, or even through IV access.

Changes in the Integumentary System

Collagen (the substance that makes skin strong) and elastin (the substance that makes the skin pliable) decrease as people age. This makes the skin wrinkled, thinner, less elastic, and more susceptible to injury.

Because the elasticity of the skin has declined, bruising becomes more common because the peripheral blood vessels cannot constrict and stop the bleeding as quickly. This causes a greater number of bruises as well as large hematomas from minimal trauma. The healing process takes longer as people age because of a decrease in the blood flow to the capillaries.

The blood vessels that supply the skin also provide less oxygenated blood at the cellular level. As a result of the skin's lower metabolism, epidermal cells develop more slowly and do not replace outgoing cells as quickly as with younger skin. Older patients, therefore, are at higher risk for secondary infection after the skin breaks, for skin tumors, and for fungal or viral infections of the skin.

In addition, as a person ages, the sebaceous glands produce less oil, making the skin drier. Sweat gland activity also decreases, hindering the ability to sweat and to regulate heat. Subcutaneous fat also becomes thinner. For these two reasons, you may often see geriatric patients wearing multiple layers of clothing.

Pressure Ulcers

The thinning of subcutaneous fat makes bedsores or pressure ulcers more common in an older, bedridden patient. These sores, also called **decubitus ulcers**, form when a person lies in the same position for too long, causing decreased blood flow to an area of already thin skin, which results in tissue death and the development of a pressure ulcer. Therefore, persons confined to a bed or stationary position need special care and a regular regimen of documented position changes every 1 to 2 hours.

Possible risk factors include brain or spinal cord injury, neuromuscular disorders, and nutritional problems. These ulcers are exacerbated by fecal and urinary incontinence, particularly when the patient is exposed to saturated materials for a prolonged time. You should be particularly aware of pressure ulcers during spinal motion restriction and ensure that padding is adequate throughout the patient's posterior side. Pressure ulcers are most commonly located on the lower legs, sacrum, greater trochanter, and the gluteal muscles.

Pressure ulcers can be classified as follows:

- **Stage 1.** A persistent area of skin redness (without a break in the skin) that does not disappear when pressure is relieved (**FIGURE 37-6**).
- **Stage 2.** A partial thickness of skin is lost and may appear as an abrasion, blister, or shallow crater.
- **Stage 3.** A full thickness of skin is lost, exposing the subcutaneous tissues; presents as a deep crater with or without undermining adjacent tissue.
- **Stage 4.** Full thickness of skin and subcutaneous tissues are lost, exposing muscle or bone.

Prehospital treatment for pressure ulcers is mostly basic life support care. However, ulcers that remain untreated can evolve into a source of substantial infection and potentially result in sepsis. When you observe pressure ulcers that suggest

FIGURE 37-6 A decubitus ulcer. This sore is in stage 1, meaning it is in the early stages of development.

© Charles Stewart MD, EMDM MPH.

infection in a patient, you should monitor the patient's body temperature and vital signs, administer oxygen, establish an IV line, and consider administration of a fluid bolus.

Homeostatic and Other Changes

Homeostasis is the process by which the body maintains a constant internal environment. Many homeostatic mechanisms work on a feedback principle, much like the thermostat in a house—that is, a change in the internal environment feeds back to the control system to induce a corrective response. For example, when the body temperature starts to rise, temperature sensors are activated, which in turn activate compensatory responses. Cutaneous blood vessels dilate, and excess heat is transferred from the body to the environment.

With aging, a progressive loss of these homeostatic capabilities occurs. Therefore, a specific illness or injury in older adults is more likely to result in generalized deterioration. For example, the thirst mechanism that ordinarily protects a person from dehydration becomes depressed in older adults. Likewise, temperature-regulating mechanisms tend to become disordered, which, when combined with integumentary changes, makes older patients more vulnerable to environmental stresses such as heat exhaustion and accidental hypothermia after relatively minor exposures. A defect in temperature regulation also may account for the absence of a febrile response to illness in some older adults. Infections that would ordinarily produce high fever, such as pneumococcal pneumonia, may produce only a low-grade or no fever in older adults.

The regulatory system that manages the blood glucose level similarly becomes impaired with increasing age, such that an elevated blood glucose level occurs quite commonly in older patients. Ordinarily, moderate hyperglycemia does no harm, but overly aggressive treatment of this problem may produce damaging hypoglycemia.

Words of Wisdom

A specific illness or injury in an older person is more likely to result in generalized deterioration.

Toxicology

Several pathophysiologic changes cause older people to be susceptible to toxicity. These include decreased kidney function, altered GI absorption, and decreased vascular flow in the liver, which alters metabolism and excretion. The kidneys undergo many changes with age. Decreased liver function makes it harder for the liver to detoxify the blood and eliminate substances such as medications and alcohol. These metabolic issues also can make it difficult for physicians to determine the appropriate dosage for new medications.

Older people account for 34% of prescribed medication use and 30% of over-the-counter (OTC) medication use.²¹ Typical OTC medicines used by older people include aspirin, antacids, cough syrups, and decongestants. Many people believe OTC medications cannot be dangerous, but these medications can have negative effects when mixed with each other and/or with herbal substances, alcohol, and prescription medications.

Older patients are often prescribed multiple medications. **Polypharmacy**, or the use of multiple medications by one patient, is a common finding in geriatric patients. People aged 65 years and older account for more than one-third of the prescribed medications in the United States even though they only comprise 13% of the population. The introduction of integrated health systems and computerized databases have helped to greatly reduce the incidence of multiple prescriptions of the same medication from varying physicians or hospitals. Of course, this does not affect samples that may be given to the patient for a trial period.

Medication interactions and noncompliance with instructions for taking prescribed drugs are common and may contribute to the patient's symptoms or problem. Medication noncompliance may occur because of financial challenges; inability to open containers; or impaired cognitive, vision, and hearing ability. If you suspect medication noncompliance, you should check prescription dates and the number of pills available.

The geriatric population is more likely to have cases of polypharmacy because older people are affected most by the process of aging. Physiologic factors known to be true about the hepatic and renal functions of excretion and metabolism

of medications can change in the face of multiple prescriptions being consumed at once. Always be mindful of this issue when obtaining the patient's medication history.

Assessment of Geriatric Medical Emergencies

Any time you assess a patient, start with the same basic approach: scene size-up, primary survey, history taking, secondary assessment, and reassessment. Assessing an older patient is no different; however, there are some issues that may require you to modify your approach to the primary survey or become more aware of some conditions that may affect older patients.

Scene Size-up

Begin by ensuring scene safety. Will you need assistance? How many patients do you have? Have you taken proper standard precautions?

When you first arrive at a patient's residence, look for important clues to determine not only your safety, but also that of the patient. The environment will provide a great deal of important information if you know where to look and what to look for.

The general condition of the home will give you some important information. Are there hazards, such as steep stairs, missing or loose handrails, or other things that could cause a fall? Is it evident that the person may be having difficulty keeping the house clean? Is there evidence of adequate food, water, heat, lighting, and ventilation? Are there many pill bottles around, indicating treatment for multiple diseases? Does someone else live there who can help to answer your questions? These are important scene clues that can provide a wealth of information before you even make contact with the patient.

In a nursing home or residential care facility, you will need to locate the patient's room and find a staff member who may be able to explain why you were called. The presence of a hospital bed, oxygen tanks, or therapeutic devices can give you a clue to the patient's medical history.

The nature of illness (NOI) may be difficult to determine in older people who may have an altered

mental status or dementia. Often it is someone other than the patient who called, so you must ask the family member, caregiver, or bystander why they called. Multiple and chronic disease processes may also complicate the determination of the NOI. Reports from an older person may be vague, such as weakness, dizziness, or fatigue. These could indicate a more serious problem and require more assessment. You may need to ask specifically what is different *today* or specifically why the person called to distinguish acute versus chronic problems. Chest pain, shortness of breath, and an altered level of consciousness should always be considered serious. You also may find that the patient's problem is a symptom of something more serious. For example, sudden changes in the ability to talk could indicate a stroke, or the need to sleep on five pillows could suggest early heart failure.

Primary Survey

The sequence of the primary survey is the same for pediatric, adult, and geriatric patients. However, you should not make any assumptions about an older patient's level of consciousness. Never assume that an altered mental status is normal. Always compare the patient's current level of consciousness or ability to function with the level or ability before the problem began. You may have to rely on a family member or caregiver to determine the patient's baseline level of consciousness.

Words of Wisdom

Remember that routine medications may mask signs and symptoms. A good understanding of the NOI/mechanism of injury, along with a high index of suspicion and an in-depth patient history, should guide your assessment and subsequent care. For example, many patients take beta-blockers that prevent the normal sympathetic response of raising pulse and respirations and mask the changes that would be expected from certain conditions (such as a tachycardic response to severe blood loss).

The general impression is an important aspect of all patient assessment. As you approach the patient, you should be able to tell if the patient is generally in stable or unstable condition. You will
